Severe intestinal inflammation often causes vomiting that is difficult to control. Central-acting antiemetics (e.g., dolasteron, ondansetron, maropitant, or prochlorperazine; see Table 30-3) are more likely to be effective than peripheral-acting drugs. The animal should be well hydrated before receiving phenothiazine derivatives, which dilate blood vessels and can produce hypotension.

Although food is typically withheld from animals with severe enteritis to "rest" the intestinal tract, such starvation may be detrimental. Administering even small amounts of food to the intestines helps them recover sooner and prevent breakdown of the mucosal barrier to bacteria. Denying any oral intake is occasionally necessary in animals in which eating causes severe vomiting or explosive diarrhea with substantial fluid loss. However, if feeding does not make the pet's vomiting and diarrhea *much* worse, feeding small amounts of food is probably more beneficial than withholding food. Frequent, small feedings of easily digested, nonirritative foods (e.g., cottage cheese, boiled chicken, potato) is the most common approach. If food must be withheld, it should be reoffered as soon as possible. Some animals with severe enteritis may need parenteral nutrition to establish a positive nitrogen balance.

If the animal is febrile or neutropenic or has systemic inflammatory response syndrome (SIRS) (e.g., septic shock), broad-spectrum systemic antibiotics (e.g.,  $\beta$ -lactam antibiotic plus an aminoglycoside) are indicated (see the discussion of drugs used in gastrointestinal disorders, pp. 409–410). The clinician should observe for hypoglycemia, especially in young animals. Adding dextrose (2.5% to 5%) to the intravenous fluids or administering an intravenous bolus of 50% dextrose (2 to 5 ml/kg) may be necessary to counter hypoglycemia.

If the cause of the diarrhea is unknown, the clinician should assume it to be infectious and disinfect the premises accordingly. Bleach diluted in water (i.e., 1:32) destroys parvovirus and many other infectious agents causing diarrhea. Animals must not be injured by inappropriate contact with such disinfectants. Personnel coming in contact with the animals, cages, and litter should wear protective clothing (e.g., boots, gloves, gowns) that can be discarded or disinfected when leaving the area.

After the enteropathy appears to be clinically resolved, the animal is gradually returned to its normal diet over a 5- to 10-day period. If this change is associated with more diarrhea, then the switch is postponed for another 5 days.

#### Prognosis

The prognosis depends on the animal's condition and can be influenced by its age and other gastrointestinal (GI) problems. Very young or emaciated animals and those with SIRS or substantial intestinal parasite burdens have a more guarded prognosis. Intussusception may occur secondary to acute enteritis, thus worsening the prognosis.

# **ENTEROTOXEMIA**

#### Etiology

The cause is assumed to be bacterial, although causative organisms are almost never isolated.

#### **Clinical Features**

An acute onset of severe, often mucoid-bloody diarrhea that may be associated with vomiting is typical. In severe cases mucus casts of the intestines are expelled, making it appear as if the intestinal mucosa is being lost. In contrast to animals with acute enteritis, these patients usually feel quite ill and may exhibit symptoms of shock early in the course of the disease. CBCs typically reveal a neutrophilic leukocytosis, often with a left shift and sometimes with white blood cell (WBC) toxicity.

# Diagnosis

Exclusion of other causes by history and physical examination coupled with severe WBC changes (e.g., toxicity, left shift) on the CBC allow for presumptive diagnosis. The pet should be checked for intestinal parasites, which may be contributing to the problem. Fecal cultures are rarely useful diagnostically.

#### **Treatment**

These patients typically need aggressive intravenous (IV) fluid therapy plus broad-spectrum antibiotic therapy (e.g., ticarcillin plus clavulinic acid). The serum albumin concentration must be monitored and colloids given if needed. Disseminated intravascular coagulation (DIC) may require plasma and/or heparin therapy.

# **Prognosis**

The prognosis depends on how ill the patient is at presentation.

#### DIETARY-INDUCED DIARRHEA

# **Etiology**

Dietary causes of diarrhea are common, especially in young animals. Poor-quality ingredients (e.g., rancid fat), bacterial enterotoxins or mycotoxins, allergy or intolerance to ingredients, or inability of the animal to digest normal foods are common causes. The latter mechanism revolves around intestinal brush border enzymes that are produced in response to the presence of substrates (e.g., disaccharidases). If the diet is suddenly changed, some animals (especially puppies and kittens) are unable to digest or absorb certain nutrients until the intestinal brush border adapts to the new diet. Other animals may never be able to produce the necessary enzymes (e.g., lactase) to digest certain nutrients (e.g., lactose).

# **Clinical Features**

Diet-induced diarrhea occurs in both dogs and cats. The diarrhea tends to reflect small intestinal dysfunction (i.e., there is usually no fecal blood or mucus) unless there is colonic involvement. The diarrhea usually starts shortly after the new diet is initiated (e.g., 1 to 3 days) and is mild to moderate in severity. Affected animals infrequently have other signs unless parasites or complicating factors are present.

# Diagnosis

History and physical and fecal examinations are used to eliminate other common causes. If diarrhea occurs shortly after a suspected or known dietary change (e.g., after the pet is brought home), a tentative diagnosis of diet-induced disease is reasonable. However, the pet may also be showing the first clinical signs of a recently acquired infection. The animal should always be checked for intestinal parasites because they may contribute to the problem even when they are not the principal cause.

#### **Treatment**

A bland diet (e.g., boiled potato plus boiled skinless chicken) fed in multiple, small feedings (see p. 397) usually causes resolution of the diarrhea in 1 to 3 days. Once the diarrhea resolves, the diet can be gradually changed back to the pet's regular diet.

# **Prognosis**

The prognosis is usually excellent, unless a very young animal with minimal nutritional reserves becomes emaciated, dehydrated, or hypoglycemic.

## INFECTIOUS DIARRHEA

#### **CANINE PARVOVIRAL ENTERITIS**

# Etiology

There are two types of parvoviruses that infect dogs. Canine parvovirus-1 (CPV-1), also known as "minute virus of canines," is a relatively nonpathogenic virus that sometimes is associated with gastroenteritis, pneumonitis, and/or myocarditis in puppies 1 to 3 weeks old. Canine parvovirus-2 (CPV-2) is responsible for classic parvoviral enteritis. CPV-2 usually causes signs 5 to 12 days after the dog is infected via the fecal-oral route, and it preferentially invades and destroys rapidly dividing cells (i.e., bone marrow progenitors, intestinal crypt epithelium).

# **Clinical Features**

The virus has mutated since it was first recognized, and the most recently recognized mutations, CPV-2b, may be more pathogenic in some dogs. CPV-2b and the even more recently identified CPV-2c can also infect cats. The clinical signs depend on the virulence of the virus, the size of the inoculum, the host's defenses, the age of the pup, and the presence of other enteric pathogens (e.g, parasites). Doberman Pinschers, Rottweilers, Pit Bulls, Labrador Retrievers, and German Shepherd dogs may be more susceptible than other breeds. Viral destruction of intestinal crypts may produce villus collapse, diarrhea, vomiting, intestinal bleeding, and subsequent bacterial invasion; however, some animals have mild or even subclinical disease. Many dogs are initially presented because of depression, anorexia, and/or vomiting (which can resemble foreign object ingestion) without diarrhea. Diarrhea is often absent for the first 24 to 48 hours of illness and may not be bloody if and when it does occur. Intestinal protein loss may occur secondary to inflammation, causing hypoalbuminemia. Vomiting is usually prominent and may be severe enough to cause esophagitis. Damage to bone marrow progenitors may produce transient or prolonged neutropenia, making the animal susceptible to serious bacterial infection, especially if a damaged intestinal tract allows bacteria access to the body. Fever and/or septic shock (i.e., systemic inflammatory response syndrome) are common in severely ill dogs but are often absent in less severely affected animals. Puppies that are infected *in utero* or before 8 weeks of age may develop myocarditis.

# **Diagnosis**

Diagnosis is often tentatively made on the basis of history and physical examination findings. Neutropenia is suggestive but is neither sensitive nor specific for canine parvovirus enteritis; salmonellosis or any overwhelming infection can cause similar changes in the CBC. Regardless of whether diarrhea occurs, infected dogs shed large numbers of viral particles in the feces (i.e., >109 particles/g). Therefore ELISA for CPV-2 in the feces is the best diagnostic test. Vaccination with a modified live parvoviral vaccine may cause a weak positive result for 5 to 15 days after vaccination. However, the ELISA results may be negative if the assay is performed early in the clinical course of the disease, and the clinician should not hesitate to repeat this test in dogs that seem likely to have parvoviral enteritis but that initially have negative findings. Shedding decreases rapidly and may be undetectable 10 to 14 days after infection. The real advantage to testing is that either a presumptive diagnosis of parvoviral enteritis is confirmed or other diseases that can mimic parvovirus but require different therapy (e.g., salmonellosis, intussusception) must be considered. Electron microscopic evaluation of feces detects the presence of the virus; however, CPV-1 (which is usually nonpathogenic except perhaps in neonates) is morphologically indistinguishable from CPV-2. If the dog dies, there are typical histologic lesions (i.e., crypt necrosis), and fluorescent antibody and in situ hydridization techniques can establish a definitive diagnosis.

#### **Treatment**

Treatment of canine parvoviral enteritis is fundamentally the same as for any severe, acute, infectious enteritis (see p. 441). Fluid and electrolyte therapy is crucial and is typically combined with antibiotics (Box 33-1). Most dogs will live if they can be supported long enough. However, very young puppies, dogs in severe septic shock, and certain breeds seem to have more problems and may have a more guarded prognosis. Mistakes include inadequate fluid therapy (common), overzealous fluid administration (especially in dogs with severe hypoproteinemia), failure to administer glucose to hypoglycemic patients, failure to supplement adequate potassium, unrecognized sepsis, and unsuspected concurrent GI disease (e.g., parasites, intussusception).

If the serum albumin concentration is less than 2.0 g/dl, it is advantageous to administer plasma. Colloids such as hetastarch may be substituted for plasma, but they do not contain antibodies that might be beneficial. Antibiotic therapy is needed if evidence of infection (i.e., fever, septic shock) exists or there is risk of infection (i.e., severe neutropenia). If the animal is neutropenic but afebrile, the admin-

BOX 33-1

#### General Guidelines for Treatment of Canine Parvoviral Enteritis\*

#### Fluids†‡

Administer balanced electrolyte solution with 30-40 mEq potassium chloride/L.

Calculate maintanence requirements (i.e., 66 ml/kg/day with dogs <5 kg needing up to 80 ml/kg/day).

Estimate deficit (better to slightly overestimate rather than underestimate the deficit).

Dogs with very mild cases may receive subcutaneous fluids (intravenous fluids still preferred), but watch for sudden worsening of the disease.

Dogs with moderate to severe cases should receive fluids via intravenous or intramedullary route.

Add 2.5%-5% dextrose to the intravenous fluids if hypoglycemia or systemic inflammatory response syndrome is present or is a risk.

Administer plasma or hetastarch if dog has serum albumin ≤2.0 g/dl.

Plasma: 6-10 ml/kg over 4 hours; repeat until the desired serum albumin concentration is attained

Hetastarch: 10-20 ml/kg

#### Antibiotics†

Administer to febrile or severely neutropenic dogs.

Prophylactic antibiotics for nonfebrile neutropenic patients (e.g., cefazolin).

Broad-spectrum antibiotics for febrile, neutropenic patients (e.g., ticarcillin/clavulinic acid plus amikacin).

#### **Antiemetics**

Given if needed:

Serotonin receptor antagonists

- Dolasetron
- Ondansetron

Maropitant (minimal clinical experience at the time of this writing)

Metoclopramide (constant rate infusion is more effective than intermittent bolusing)

H<sub>2</sub>-receptor antagonists (for antidyspepsia effects)

• Famotidine

## **Anthelmintics**

Pyrantel (should be given after feeding)

Ivermectin (this drug is absorbed in the oral mucous membranes; do not give to breeds that are likely to have adverse effects, such as Collies, Old English Sheepdogs, etc.)

#### **Dogs With Secondary Esophagitis**

If regurgitation occurs in addition to vomiting, administer: H<sub>2</sub>-receptor antagonists (injectable) Sucralfate (Carafate) slurry

# Special Nutritional Therapy

Try to feed dog small amounts as soon as feeding does not cause major exacerbation in vomiting.

"Microenteral" nutrition (slow drip of enteral diet administered via nasoesophageal tube) if dog refuses to eat and administration does not make vomiting worse

Administer parenteral nutrition if prolonged anorexia occurs

Peripheral parenteral nutrition is more convenient than total parenteral nutrition

#### **Monitor Physical Status**

Physical examination (1-3 times per day depending on severity of signs)

Body weight (1-2 times per day to assess changes in hydration status)

Potassium (every 1-2 days depending on severity of vomiting/diarrhea)

Serum protein (every 1-2 days depending on severity of signs)

Glucose (every 4-12 hours in dogs that have systemic inflammatory response syndrome or were initially hypoglycemic)

Packed cell volume (every 1-2 days)

White blood cell count: either actual count or estimated from a slide (every 1-2 days in febrile animals)

# Controversial Therapies

Recominant feline IFN-ώ: One report suggests that this therapy was useful.

Tamiflu (anecdotally beneficial if used early in the course of the disease)

Flunixin Meglumine: Sometimes used for patients with systemic inflammatory response syndrome, but perforation and bleeding are significant risks.

istration of a first-generation cephalosporin is reasonable. If the animal is in septic shock (i.e., systemic inflammatory response syndrome), then an antibiotic combination with a broad aerobic and anerobic spectrum is recommended (e.g., ticarcillin or ampicillin plus amikacin or enrofloxacin). Aminoglycosides should not be administered until the patient is rehydrated and renal perfusion is re-established. Caution should be used when administering enrofloxacin to young, large-breed dogs lest cartilage damage occur. Severe vomiting complicates therapy and may require administration of

<sup>\*</sup> The same guidelines generally apply to dogs with other causes of acute enteritis/gastritis.

<sup>†</sup> Usually the first considerations when an animal is presented.

<sup>‡</sup>A history of decreased intake plus increased loss such as vomiting and/or diarrhea confirms dehydration, regardless of whether dog appears to be dehydrated.

dolasetron, ondansetron, or maropitant (see Table 30-3). If esophagitis occurs,  $H_2$ -receptor antagonists may be useful (see Table 30-4). Human granulocyte colony–stimulating factor (G-CSF) (5 µg/kg q24h) to increase neutrophil numbers and tamiflu (oseltamivir phosphate) (2 mg/kg q12-24h) to combat the virus have been advocated; however, there is no evidence that either substantively benefits the patient. Flunixin meglamine has been suggested for patients in septic shock, but care must be taken lest iatrogenic ulceration/perforation occurs. Recombinant feline IFN- $\dot{\omega}$  (2.5 × 10<sup>6</sup> units per kg) has been suggested to improve the chance of survival.

If possible, feeding small amounts of liquid diet via a nasoesophageal (NE) tube seems to help the intestines to heal more rapidly. A bland diet may be fed once vomiting has ceased for 18 to 24 hours. Parenteral nutrition can be life saving for patients that are persistently unable to hold down oral food. It can be equally critical for patients unable to accept any enteral nutrition. Partial parenteral nutrition is easier and less expensive than total parenteral nutrition. The dog should be kept away from other susceptible animals for 2 to 4 weeks after discharge, and the owner should be conscientious about the disposal of feces. Vaccination of other dogs in the household should be considered.

When trying to prevent the spread of parvoviral enteritis, the clinician must remember that (1) parvovirus persists for long periods of time (i.e., months) in the environment, making it difficult to prevent exposure; (2) asymptomatic dogs may shed virulent CPV-2; (3) maternal immunity sufficient to inactivate vaccine virus may be present in some puppies; and (4) dilute bleach (1:32) is one of the few readily available disinfectants that kills the virus, but it can take 10 minutes to achieve effectiveness.

Vaccination of pups should generally commence at 6 to 8 weeks of age. The antigen density and immunogenicity of the vaccine as well as the amount of antibody transferred from the bitch determine when the pup can be successfully immunized. Inactivated vaccines generally are not as successful as attenuated vaccines, and giving a series of these vaccinations seems best. Attenuated vaccines are generally more successful in producing a long-lasting immunity. When the immune status of the pup is unknown, administering an attenuated vaccine at 6, 9, and 12 weeks of age is usually successful. If vaccination before 5 to 6 weeks of age is deemed necessary, an inactivated vaccine is safer. Regardless of the vaccine used, it appears that there is typically a 2- to 3-week window during which the pup is susceptible to parvovirus infection and yet cannot be successfully immunized. Annual revaccination is generally recommended for parvovirus, although it is possible that vaccination every 3 years may be sufficient after the initial series as a puppy. Adults that were previously not vaccinated usually receive two doses 2 to 4 weeks apart. There is no strong evidence that parvoviral vaccination should be given separately from modified-live canine distemper vaccinations. However, modified-live vaccinations should not be administered to patients younger

than 5 weeks of age or those suspected of incubating or being affected with distemper.

If parvoviral enteritis develops in one dog in a multipledog household, it is reasonable to administer booster vaccinations to the other dogs, preferably using an inactivated vaccine in case they are incubating the infection at the time of immunization. If the client is bringing a puppy into a house with a dog that has recently had parvoviral enteritis, the puppy should be kept elsewhere until it has received its immunizations.

# **Prognosis**

Dogs treated in a timely fashion with proper therapy typically live, especially if they survive the first 4 days of clinical signs. The possible sequela of intussusception may cause persistent diarrhea in pups recovering from the viral infection. Dogs that have recovered from CPV-2 enteritis develop long-lived immunity that may be lifelong. Whether immunization against CPV-1 will be needed is unknown.

#### FELINE PARVOVIRAL ENTERITIS

# **Etiology**

Feline parvoviral enteritis (feline distemper, feline panleukopenia) is caused by feline panleukopenia virus (FPV), which is distinct from CVP-2b. However, CPV-2a, CPV-2b, and CPV-2c can infect cats and cause disease.

# **Clinical Features**

Many infected cats never show clinical signs of disease. Signs in affected cats are usually similar to those described for dogs with parvoviral enteritis. Kittens affected *in utero* may develop cerebellar hypoplasia.

## Diagnosis

Diagnosis is similar to that described for canine parvovirus. The ELISA test for fecal CPV is also a good test for feline parvovirus. However, it is important to note that the test may be positive for only 1 to 2 days after infection, and by the time the cat is clinically ill, this test may not be able to detect viral shedding in the feces.

#### **Treatment**

Cats with parvoviral infection are treated much in the same way as described for dogs with the disease. A major difference between dogs and cats centers on immunization: Parvoviral vaccine seems to engender a better protective response in cats than in dogs. However, kittens younger than 4 weeks of age should not be vaccinated with modified live virus vaccines lest cerebellar hypoplasia occur. Also, the vaccine cannot be administered orally, but intranasal adminstration is effective.

# **Prognosis**

As with dogs, many affected cats live if overwhelming sepsis is prevented and they can be supported long enough.

## **CANINE CORONAVIRAL ENTERITIS**

# Etiology

Canine coronaviral enteritis occurs when coronavirus invades and destroys mature cells on the intestinal villi. Because intestinal crypts remain intact, villi regenerate more quickly in dogs with coronaviral enteritis than in dogs with parvoviral enteritis; bone marrow cells are not affected.

#### **Clinical Features**

Coronaviral enteritis is typically less severe than classic parvoviral enteritis and rarely causes hemorrhagic diarrhea, septicemia, or death. Dogs of any age may be infected. Signs usually last less than 1 to  $1^{1}/_{2}$  weeks, and small or very young dogs may die as a result of dehydration or electrolyte abnormalities if they are not properly treated. Dual infection with parvovirus may produce a high incidence of morbidity and mortality.

# Diagnosis

Because canine coronaviral enteritis is usually much less severe than many other enteritides, it is seldom definitively diagnosed. Most dogs are treated symptomatically for acute enteritis until they improve. Electron microscopic examination of feces obtained early in the course of the disease can be diagnostic. However, the virus is fragile and easily disrupted by inappropriate handling of the feces. A history of contagion and elimination of other causes are reasons to suspect canine coronaviral enteritis.

#### Treatment

Fluid therapy, motility modifiers (see Chapter 30), and time should resolve most cases of coronaviral enteritis. Symptomatic therapy (see p. 441) is usually successful except, perhaps, for very young animals. A vaccination is available but of uncertain value except, perhaps, in animals at high risk of infection (e.g., those in infected kennels or dog shows).

# **Prognosis**

The prognosis for recovery is usually good.

#### FELINE CORONAVIRAL ENTERITIS

Infections in adults are often asymptomatic, whereas kittens may have mild, transient diarrhea and fever. Deaths are rare, and the prognosis for recovery is excellent. This disease is important because (1) affected animals seroconvert and may become positive on feline infectious peritonitis serologic analysis and (2) mutation by the feline coronavirus may be the cause of feline infectious peritonitis.

# FELINE LEUKEMIA VIRUS-ASSOCIATED PANLEUKOPENIA (MYELOBLASTOPENIA)

# **Etiology**

FeLV-associated panleukopenia (myeloblastopenia) may actually be caused by co-infection with FeLV and FPV. The intestinal lesion histologically resembles that produced

by feline parvovirus. The bone marrow and lymph nodes are not consistently affected as they are in cats with parvoviral enteritis.

#### **Clinical Features**

Chronic weight loss, vomiting, and diarrhea are common. The diarrhea often has characteristics of large bowel disease. Anemia is common.

# Diagnosis

Finding FeLV infection in a cat with chronic diarrhea is suggestive. Cats are typically neutropenic. Histologic lesions of FPV in a cat with FeLV should be definitive.

#### **Treatment**

Symptomatic therapy (fluid/electrolyte therapy, antibiotics, antiemetics, and/or highly digestible bland diets as needed) and elimination of other problems that compromise the intestines (e.g., parasites, poor diet) may be beneficial.

# **Prognosis**

This disease has a poor prognosis because of other FeLV-related complications.

# FELINE IMMUNODEFICIENCY VIRUS-ASSOCIATED DIARRHEA

# **Etiology**

FIV may be associated with severe, purulent colitis. The pathogenesis is unclear and may involve multiple mechanisms.

#### **Clinical Features**

Severe large bowel disease is common and can occasionally result in colonic rupture. These animals generally appear ill, whereas most cats with chronic large bowel disease caused by inflammatory bowel disease (IBD) or dietary intolerance seemingly feel fine.

# Diagnosis

Detection of antibodies to FIV plus severe, purulent colitis allows presumptive diagnosis.

#### Treatment

Therapy is supportive (e.g., fluids/electrolytes, antiemetics, antibiotics, and/or highly digestible bland diets as needed).

#### **Prognosis**

The long-term prognosis is very poor, although some cats can be maintained for months.

# SALMON POISONING/ELOKOMIN FLUKE FEVER

# Etiology

Salmon poisoning is caused by *Neorickettsia helminthoeca*. Dogs are infected when they eat fish (primarily salmon) infected with a fluke (*Nanophyetus salmincola*) that carries the rickettsia. The rickettsia spreads to the intestines and

most lymph nodes, causing inflammation. This disease is principally found in the Pacific northwestern United States because the snail intermediate host (Oxytrema silicula) for N. salmincola lives there. The Elokomin fluke fever agent may be a strain of N. helminthoeca.

#### **Clinical Features**

Dogs, not cats, are affected. The severity of signs varies and typically consists of initial fever that eventually falls and becomes subnormal. Fever is followed by anorexia and weight loss, which may also involve vomiting and/or diarrhea. The diarrhea is typically small bowel but may become bloody.

# Diagnosis

Presumptive diagnosis is usually based on the animal's habitat plus a history of recent consumption of raw fish or exposure to streams or lakes. Finding *Nanophyetus* spp. ova (operculated trematode ova) in the stool is very suggestive, and finding rickettsia in fine-needle aspirates of enlarged lymph nodes is confirmatory.

#### **Treatment**

Treatment consists of symptomatic control of dehydration, vomiting, and diarrhea and elimination of the rickettsia and fluke. Tetracycline, oxytetracycline, doxycycline, or chloramphenicol (see Chapter 93) eliminates the rickettsia. The fluke is killed with praziquantel (see Table 30-7).

# **Prognosis**

The prognosis depends on the clinical severity at the time of diagnosis. Most dogs respond favorably to tetracyclines and supportive therapy. The key to success is awareness of the disease. Untreated salmon poisoning has a poor prognosis.

# BACTERIAL DISEASES: COMMON THEMES

The following bacterial diseases all have certain aspects in common. First, all of these bacteria may be found in feces from clinically normal dogs and cats. Simply growing the bacteria or finding toxin produced by the bacteria in the patient's feces are insufficient by themselves to definitively diagnose intestinal disease as being caused by this particular organism. Diagnosis can be made only by finding clinical disease consistent with a particular organism, evidence of the organism or its toxin, eliminating other causes of the clinical signs, and seeing the expected response to appropriate therapy. If the clinician undertakes culture, it is crucial to call the laboratory ahead of time, tell staff members what is being sought through culture, and follow their instructions regarding submission of the sample.

The problems with making a diagnosis using the previously mentioned criteria are obvious, and caution is warranted before making definitive statements regarding cause and effect. In many cases, the best chance of making a definitive diagnosis involves following the guidelines described

and using molecular techniques on isolates to demonstrate toxin production.

#### **CAMPYLOBACTERIOSIS**

# Etiology

There are several species of Campylobacter. Campylobacter jejuni is the species routinely associated with GI disease, although Campylobacter upsaliensis has been implicated. These organisms prefer high temperatures (i.e., 39° to 41° C); hence poultry is probably a reservoir. These organisms are found in the intestinal tract of healthy dogs and cats.

#### **Clinical Features**

Symptomatic campylobacteriosis is principally diagnosed in animals younger than 6 months old living in crowded conditions (e.g., kennels, humane shelters) or as a nosocomial infection. Mucoid diarrhea (with or without blood), anorexia, and/or fever are the primary signs. Campylobacteriosis tends to be self-limiting in dogs, cats, and people; however, it occasionally causes chronic diarrhea.

# Diagnosis

Occasionally, classic *Campylobacter* forms may be found during cytologic examination of a fecal smear (i.e., "commas," "seagull wings"). This cytology is thought to be specific but of uncertain sensitivity. Polymerase chain reaction (PCR) analysis of feces is available.

# **Treatment**

If campylobacteriosis is suspected, erythromycin (11 to 15 mg/kg administered orally q8h) or neomycin (20 mg/kg administered orally q12h) is usually effective.  $\beta$ -lactam antibiotics (i.e., penicillins, first-generation cephalosporins) are often ineffective. The length of treatment necessary for cure has not been firmly established. The animal should be treated for at least 1 to 3 days beyond resolution of clinical signs; however, antibiotic therapy may not eradicate the bacteria, and reinfection is likely in kennel conditions. Chronic infections may require prolonged therapy (e.g., weeks).

This bacterium is potentially transmissible to people, and there are cases in which there is convincing evidence of transmission from pets to people. Infected dogs and cats should be isolated, and individuals working with the animal or its environment or wastes should wear protective clothing and wash with disinfectants.

#### **Prognosis**

With appropriate antibiotic therapy, the prognosis for recovery is good.

# **SALMONELLOSIS**

# **Etiology**

There are numerous Salmonella serotypes that may cause disease; Salmonella typhimurium is one of the serovars that is more commonly associated with disease. The bacteria may originate from animals shedding the organism (e.g., infected

dogs and cats) or from contaminated foods (especially poultry and eggs).

# **Clinical Features**

Salmonella spp. may produce acute or chronic diarrhea, septicemia, and/or sudden death, especially in very young or geriatric animals. Salmonellosis in young animals can produce a syndrome that closely mimics parvoviral enteritis (including severe neutropenia), which is one reason that ELISA testing for parvovirus is useful. The fact that salmonellosis occasionally develops during or after canine parvoviral enteritis makes the situation more confusing.

# **Diagnosis**

Culture of *Salmonella* spp. from normally sterile areas (e.g, blood) confirms that it is causing disease. Identification by PCR can be a sensitive method of diagnosis.

#### **Treatment**

Treatment depends on the clinical signs. Animals with diarrhea as the sole sign may need only supportive fluid therapy (including plasma in hypoalbuminemic patients). Nonsteroidal drugs (to lessen intestinal secretion) and lactulose have been used in such patients. Antibiotics are of dubious value and might promote a carrier state. Septicemic (i.e., febrile) animals should receive supportive therapy and parenteral antibiotics as determined by susceptibility testing, but quinolones, potentiated sulfa drugs, amoxicillin, and chloramphenicol are often good initial choices (see the discussion of drugs used in gastrointestinal disorders, pp. 409–410). Aggressive plasma therapy might be beneficial in such patients.

Infected animals are public health risks (especially for infants and older adults) and should be isolated from other animals, at least until they are asymptomatic. Even when signs disappear, reculturing of feces is reasonable to ensure that shedding has stopped. Individuals in contact with the animal, its environment, and its waste should wear protective clothing and wash with disinfectants such as phenolic compounds and bleach (1:32 dilution).

# **Prognosis**

The prognosis is usually good in animals with only diarrhea but guarded in septicemic dogs and cats.

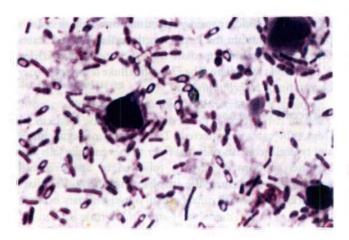

# **CLOSTRIDIAL DISEASES**

# **Etiology**

Clostridium perfringens and Clostridium difficile can be found in clinically normal dogs but appear to cause diarrhea in some. For *C. perfringens* to produce disease, the bacteria must possess the ability to produce toxin, and environmental conditions must be such that toxin is produced.

# **Clinical Features**

C. perfringens apparently may produce an acute, bloody, selflimiting nosocomial diarrhea; an acute, potentially fatal

IG 33-1

Photomicrograph of air-dried canine feces stained with Diff-Quik. Numerous spores are seen as clear vacuoles in darkly stained rods. (Magnification ×1000.)

hemorrhagic diarrhea; or a chronic large bowel or small bowel (or both) diarrhea (with or without blood or mucus). This clostridial disease is primarily recognized in dogs. Disease associated with *C. difficile* is poorly characterized in small animals but may include large bowel diarrhea, especially after antibiotic therapy.

# **Diagnosis**

In particular, finding spore-forming bacteria on fecal smears (Fig. 33-1) is not diagnostic. Commercially available toxin assays for *C. difficile* toxin have not been validated for the dog or cat, and results do not necessarily correlate with the patient's clinical condition. Determining that the patient has large bowel diarrhea without weight loss or hypoalbuminemia, elimination of other causes, and resolution of signs when treated appropriately (see next paragraph) is typically the basis for presumptive diagnosis.

#### **Treatment**

If *C. perfringens* disease is suspected, the animal may be treated with tylosin or amoxicillin, and response is expected shortly. Some animals are cured after a 1- to 3-week course of therapy. However, antibiotic treatment does not necessarily eliminate the bacteria, and some dogs need indefinite therapy. Tylosin (20 to 80 mg/kg/day, divided, q12h) or amoxicillin (22 mg/kg q12h) seems to be effective and yet has minimal adverse effects in these animals. Some animals can eventually be maintained with once daily or every-otherday antibiotic therapy. Some dogs with chronic diarrhea seemingly caused by *C. perfringens* respond well to fibersupplemented diets. Metronidazole is not as consistently effective as tylosin or amoxicillin. The prognosis is good, and there is no obvious public health risk, although there is anecdotal evidence of transmission between people and dogs.

If disease caused by *C. difficile* is suspected, supportive fluid and electrolyte therapy may be necessary depending on the severity of signs. Metronidazole should be effective in killing this bacterium, but one must be sure to use a sufficiently

high dose to achieve adequate metronidazole concentrations in the feces. Vancomycin is often used to treat people with this disease but has not generally been necessary in dogs or cats.

# **Prognosis**

The prognosis is excellent in dogs with diarrhea caused by *C. perfringens* but uncertain for those cases caused by *C. difficile*.

# MISCELLANEOUS BACTERIA

# **Etiology**

Yersinia enterocolitica, Aeromonas hydrophila, and Plesiomonas shigelloides may cause acute or chronic enterocolitis in dogs and/or cats as well as in people. However, these bacteria (especially the latter two) are uncommonly diagnosed in the United States. Y. enterocolitica is primarily found in cold environments and in pigs, which may serve as a reservoir. It is also a cause of food poisoning because of its ability to grow in cold temperatures. Enterohemorrhagic Escherichia coli (EHEC) may seemingly be associated with canine and feline diarrhea, although it does not appear to be especially common.

# **Clinical Features**

Small bowel diarrhea may be caused by any of these bacteria. Yersiniosis usually affects the colon and produces chronic large bowel diarrhea. Affected people report substantial abdominal pain.

# Diagnosis

Animals with persistent colitis, especially those that are in contact with pigs, may reasonably be cultured for *Y. enterocolitica*.

#### **Treatment**

Therapy is supportive. The affected animal should be isolated from other animals. People in contact with the animal and/or its environment and wastes should wear protective clothing and clean themselves with disinfectants. Although antibiotics intuitively seem indicated, their use has not shortened clinical disease caused by EHEC. Nonetheless, appropriate antibiotics as determined by culture and sensitivity are used (e.g., *Y. enterocolitica* is often sensitive to tetracyclines). The preferred length of antibiotic therapy has not been established, but treatment should probably be continued for 1 to 3 days beyond clinical remission.

# **Prognosis**

The prognosis is uncertain but seems to be good if the bacteria can be identified by culture and the infection treated appropriately.

# **HISTOPLASMOSIS**

# Etiology

Caused by Histoplasma capsulatum, histoplasmosis is a mycotic infection that may affect the GI, respiratory, and/or

reticuloendothelial systems, as well as the bones and eyes. Principally found in animals from the Mississippi and Ohio River valleys, it occurs in other areas as well.

# **Clinical Features**

Alimentary tract involvement is primarily found in dogs; diarrhea (with or without blood or mucus) and weight loss are common signs. The lungs, liver, spleen, lymph nodes, bone marrow, bones, and/or eyes may also be affected. Symptomatic alimentary involvement is much less common in cats, in which respiratory dysfunction (e.g., dyspnea, cough), fever, and/or weight loss are more common.

In GI histoplasmosis, the colon is usually the most severely affected segment. Diffuse, severe, granulomatous, ulcerative mucosal disease can produce bloody stool, intestinal protein loss, intermittent fever, and/or weight loss. Small intestinal involvement occasionally occurs. The disease may smolder for long periods of time, causing mild to moderate, nonprogressive signs. Occasionally, histoplasmosis causes focal colonic granulomas or is present in grossly normal-appearing colonic mucosa.

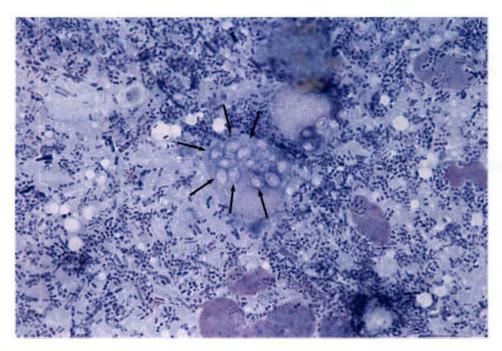

# Diagnosis

Diagnosis requires finding the yeast (Fig. 33-2), although a recent test for antigen present in urine is being evaluated. Dogs from endemic areas with chronic large bowel diarrhea are especially suspect. Protein-losing enteropathy is common in dogs with severe histoplasmosis, and hypoalbuminemia in dogs with large bowel disease is suggestive of the disease, regardless of the location.

Rectal examination sometimes reveals thickened rectal folds, which can easily be scraped with a dull curette or syringe cap to obtain material for cytologic preparations. Evaluation of colonic biopsy specimens is usually diagnostic, but special stains may be necessary. Mesenteric lymph node samples or repeated colonic biopsy is rarely required. Fundic examination occasionally reveals active chorioretinitis. Abdominal radiographs might reveal hepatosplenomegaly, and thoracic radiographs sometimes demonstrate pulmonary involvement (e.g., miliary interstitial involvement and/or hilar lymphadenopathy). Cytologic evaluation of hepatic or splenic aspirates may be diagnostic. The CBC rarely reveals yeasts in circulating WBCs. Thrombocytopenia may occur. Cytologic examination of bone marrow or of buffy coat smears may reveal the organism. Serologic tests and fecal culture for the yeast are unreliable.

#### **Treatment**

It is crucial to look for histoplasmosis before beginning empiric corticosteroid therapy for suspected canine colonic IBD. Corticosteroid therapy lessens host defenses and may allow a previously treatable case to rapidly progress and kill the animal. Itraconazole by itself or preceded by amphotericin B is often effective (see Chapter 98). Treatment should be continued long enough (i.e., at least 4 to 6 months) to lessen chances for relapse.

#### FIG 33-2

Cytologic preparation of a colonic mucosal scraping demonstrating *Histoplasma capsulatum*. Note the macrophage with numerous yeasts in the cytoplasm *(arrows)*. (Wright-Giemsa stain; magnification ×400.) (From Allen D, editor: *Small animal medicine*, Philadelphia, 1991, JB Lippincott.)

#### **Prognosis**

Many dogs can be cured if treated relatively early. Multiple organ system involvement worsens the prognosis, as does central nervous system (CNS) involvement.

#### **PROTOTHECOSIS**

# **Etiology**

Prototheca zopfii is an alga that invades tissue. It appears to be acquired from the environment, and some type of deficiency in the host's immune system might be needed for the organism to produce disease.

# **Clinical Features**

Affecting dogs and occasionally cats, protothecosis principally involves the skin, colon, and eyes but may disseminate throughout the body. Collies may be overrepresented. Colonic involvement causes bloody stools and other signs of colitis, much like histoplasmosis. Protothecosis is much less common than histoplasmosis, and the GI form primarily affects dogs.

# **Diagnosis**

Diagnosis requires demonstrating the organism (Fig. 33-3).

## **Treatment**

Most drugs work inconsistently. High doses of amphotericin B (administered via liposomes) might be useful.

# **Prognosis**

The prognosis for disseminated disease is poor because no treatment consistently works.

# **ALIMENTARY TRACT PARASITES**

## WHIPWORMS

#### Etiology

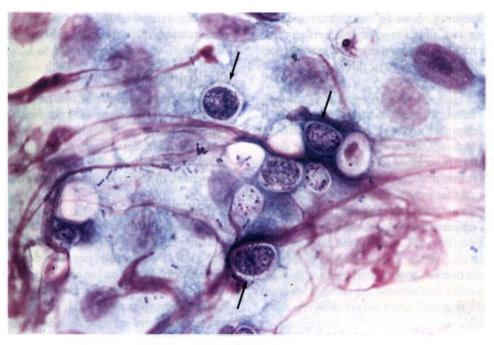

Trichuris vulpis is principally found in the eastern United States. Animals acquire the infection by ingesting ova; the adults burrow into the colonic and cecal mucosa and may cause inflammation, bleeding, and intestinal protein loss.

## **Clinical Features**

Dogs and rarely cats acquire whipworms, which produce a wide spectrum of mild to severe colonic disease that can include hematochezia and protein-losing enteropathy. Severe trichuriasis may cause severe hyponatremia and hyperkalemia, mimicking hypoadrenocorticism. Marked hyponatremia might be responsible for CNS signs (e.g., seizures). Whipworms generally do not affect cats as severely as dogs.

# **Diagnosis**

T. vulpis should always be sought in dogs with bloody stools or other colonic disease. Diagnosis is made through finding ova (Fig. 33-4) in the feces or seeing the adults at endoscopic

**FIG 33-3**Cytologic preparation of a colonic mucosal scraping demonstrating *Prototheca* spp. Note the bean-shaped structures that have a granular internal structure and appear to have a halo *(arrows)*. Photomicrograph of a fecal flotation analysis from a dog, demonstrating characteristic ova from whipworms (W), Toxocara canis (T), and Isospora spp. (I). The remaining ova are those of an unusual tapeworm, Spirometra sp. (Magnification ×250.) (Courtesy Dr. Tom

Craig, Texas A & M University.)

evaluation. However, these ova are relatively dense and float only in properly prepared flotation solutions. Furthermore, ova are shed intermittently and sometimes can be found only if multiple fecal examinations are performed.

#### **Treatment**

Because of the potential difficulty in diagnosing *T. vulpis*, it is reasonable to empirically treat dogs with chronic large bowel disease with fenbendazole or other appropriate drugs (see Table 30-7) before proceeding to endoscopy. If a dog is treated for whipworms, it should be treated again in 3 months to kill worms that were not in the intestinal lumen at the time of the first treatment. The ova persist in the environment for long periods.

# **Prognosis**

The prognosis for recovery is good.

## **ROUNDWORMS**

# Etiology

Roundworms are common in dogs (*Toxocara canis* and *Toxascaris leonina*) and cats (*Toxocara cati* and *Toxascaris leonina*). Dogs and cats can obtain roundworms from ingesting the ova (either directly or via paratenic hosts). *T. canis* is often obtained transplacentally from the mother; *T. cati* may use transmammary passage, and *T. leonina* can use intermediate hosts. Tissue migration of immature forms can cause hepatic fibrosis and significant pulmonary lesions. Adult roundworms live in the small intestinal lumen

and migrate against the flow of ingesta. They can cause inflammatory infiltrates (e.g., eosinophils) in the wall of the intestine.

#### **Clinical Features**

Roundworms may cause or contribute to diarrhea, stunted growth, a poor haircoat, and poor weight gain, especially in young animals. Runts with "potbellies" suggest severe roundworm infection. Sometimes, roundworms gain access to the stomach, in which case they may be vomited. If parasites are numerous, they may obstruct the intestines or bile duct.

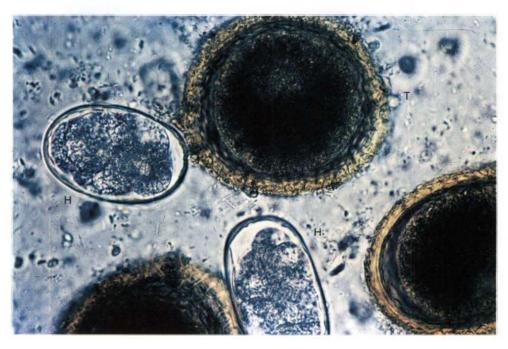

# **Diagnosis**

Diagnosis is easy because ova are produced in large numbers and are readily found by fecal flotation (Fig. 33-5; see also Fig. 33-4). Occasionally, neonates develop clinical signs of roundworm infestation but ova cannot be found in the feces. Transplacental migration results in large worm burdens, causing signs in these animals before the parasites mature and produce ova.

#### **Treatment**

Various anthelmintics are effective (see Table 30-7), but pyrantel is especially safe for young dogs and cats, particularly those with diarrhea. Affected animals should be retreated at 2- to 3-week intervals to kill roundworms that were initially in tissues but migrated into the intestinal lumen since the last treatment.

High-dose fenbendazole therapy (i.e., 50 mg/kg/day from day 40 of gestation until 2 weeks postpartum) has been sug-

Photomicrograph of a fecal flotation analysis from a dog demonstrating characteristic ova from hookworms (H) and Toxocara canis (T). (Magnification ×400.) (Courtesy Dr. Tom Craig, Texas A & M University.)

gested to reduce the somatic roundworm burden in bitches and lessen transplacental transmission to puppies. Newborn puppies can be treated with fenbendazole (100 mg/kg for 3 days), which kills more than 90% of prenatal larvae. This treatment can be repeated 2 to 3 weeks later. Preweaning puppies should be treated at 2, 4, 6, and 8 weeks of age to lessen contamination of the environment because *T. canis* and *T. cati* pose a human health risk (i.e., visceral and ocular larval migrans). Preweaning kittens should be treated at 6, 8, and 10 weeks of age.

# **Prognosis**

The prognosis for recovery is good unless the animal is already severely stunted when treated, in which case it may never attain its anticipated body size.

#### **HOOKWORMS**

# Etiology

Ancylostoma spp. and Uncinaria spp. are more common in dogs than in cats. Infestation is usually via ingestion of the ova or through transcolostral transmission; freshly hatched larvae may also penetrate the skin. The adults live in the small intestinal lumen, where they attach to the mucosa. Plugs of intestinal mucosa and/or blood is ingested, depending on the worm species. In severe infestations hookworms may be found in the colon.

#### **Clinical Features**

Dogs are more severely affected than cats. Young animals may have life-threatening blood loss or iron-deficiency anemia, melena, frank fecal blood, diarrhea, and/or failure to thrive. Older dogs rarely have disease solely caused by hookworms unless they harbor a massive infestation, but these worms may still contribute to disease caused by other intestinal problems.

#### Diagnosis

Finding ova in the feces is diagnostic (see Fig. 33-5) and easy because hookworms are prolific egg producers. However, 5- to 10-day-old puppies may be exsanguinated by transcolostrally obtained hookworms before ova appear in the feces. Such prepatent infections rarely occur in older animals that have received a sudden, massive exposure. Diagnosis is suggested by signalment and clinical signs in these animals. Iron deficiency anemia in a puppy or kitten free of fleas is highly suggestive of hookworm infestation.

#### **Treatment**

Various anthelmintics are effective (see Table 30-7). Treatment should be repeated in approximately 3 weeks to kill parasites entering the intestinal lumen from the tissues. In anemic puppies and kittens, blood transfusions may be life saving.

Application of moxidectin to pregnant bitches on day 55 of pregnancy reduces transcolostral transmission to puppies. Hookworms are a potential human health hazard (i.e., cuta-

neous larval migrans). Use of heartworm preventives containing pyrantel or milbemycin helps to minimize hookworm infestations.

# **Prognosis**

The prognosis is good in mature dogs and cats but guarded in severely anemic puppies and kittens. If the puppies or kittens are severely stunted in their growth, they may never attain their anticipated body size.

#### **TAPEWORMS**

# Etiology

Several tapeworms infect dogs and cats, the most common being *Dipylidium caninum*. Tapeworms usually have an indirect life cycle; the dog or cat is infected when it eats an infected intermediate host. Fleas and lice are intermediate hosts for *D. caninum*, whereas wild animals (e.g., rabbits) are intermediate hosts for some *Taenia* spp.

#### **Clinical Features**

Aesthetically offensive, tapeworms are rarely pathogenic in small animals, although *Mesocestoides* spp. can reproduce in the host and cause disease (e.g., abdominal effusion). The most common sign in infested dogs and cats is anal irritation associated with shed segments "crawling" on the area. Typically, the owner sees motile tapeworm segments on the feces and requests treatment. Occasionally, a segment enters an anal sac and causes inflammation. Very rarely, large numbers of tapeworms cause intestinal obstruction.

# Diagnosis

Taenia spp. and especially *D. caninum* eggs are typically confined in segments not detected by routine fecal flotations. *Echinococcus* spp. and some *Taenia* spp. ova may be found in the feces. Tapeworms are usually diagnosed when the owner reports tapeworm segments (e.g., "rice grains") on feces or the perineal area.

#### **Treatment**

Praziquantel and episprantel are effective against all species of tapeworms (see Table 30-7). Prevention of tapeworms involves controlling the intermediate hosts (i.e., fleas and lice for *D. caninum*). *Echinococcus* spp. are a human health hazard.

#### **STRONGYLOIDIASIS**

# Etiology

Strongyloides stercoralis principally affects puppies, especially those in crowded conditions. These parasites produce motile larvae that penetrate unbroken skin or mucosa; thus the animal may be infested from its own feces even before the larvae are evacuated from the colon. In this manner, animals can quickly acquire large parasitic burdens. Most animals are infested after being exposed to fresh feces containing the

motile larvae. Humane shelters and pet stores are likely sources for infestation.

# **Clinical Features**

Infested animals usually have mucoid or hemorrhagic diarrhea and are systemically ill (e.g., lethargy). Respiratory signs (i.e., verminous pneumonia) occur if parasites penetrate the lungs.

# **Diagnosis**

S. stercoralis is diagnosed by finding the larvae in fresh feces, either by direct fecal examination or by Baermann sedimentation. Strongyloides larvae must be differentiated from Oslerus spp. larvae. The feces must be fresh because old feces may contain hatched hookworm larvae, which resemble those of Strongyloides spp.

#### **Treatment**

Fenbendazole (when used for 5 days instead of 3; see Table 30-7), thiabendazole, and ivermectin are effective anthelmintics. This disease is a human health hazard because larvae penetrate unbroken skin. Immunosuppressed people are at risk for severe disease after being infected.

# **Prognosis**

The prognosis is guarded in young animals with severe diarrhea and/or pneumonia.

#### COCCIDIOSIS

#### Etiology

Isospora spp. are principally found in young cats and dogs. The pet is usually infested by ingesting infective oocysts from the environment. The coccidia invade and destroy villous epithelial cells.

# **Clinical Features**

Coccidia may be clinically insignificant (especially in an asymptomatic, older animal), or they may be responsible for mild to severe diarrhea, sometimes with blood. Rarely, a kitten or puppy may lose enough blood to require a blood transfusion.

# Diagnosis

Coccidiosis is diagnosed by finding oocysts on fecal flotation examination (see Fig. 33-4); however, repeated fecal examinations may be needed, and small numbers of oocysts do not ensure that the infestation is insignificant. These oocysts should not be confused with giardial cysts. If a necropsy is performed, multiple areas of the intestine should be sampled because the infection may be localized to one area. Occasionally, *Eimeria* oocysts will be seen in the feces of dogs that eat deer or rabbit excrement.

# Treatment

If coccidia are believed to be causing a problem, sulfadimethoxine or trimethoprim-sulfa should be administered for 10 to 20 days (see Table 30-7). The sulfa drug does not eradicate the coccidia but inhibits it so that body defense mechanisms can reestablish control. Amprolium (25 mg/kg administered orally q24h for 3 to 5 days) can be used in puppies but is not approved for use in dogs; it is potentially toxic in cats. Toltrazuril (15 mg/kg q24h for 3 days) has been found to decrease oocyst shedding, at least temporarily.

# **Prognosis**

The prognosis for recovery is usually good unless there are underlying problems that allowed the coccidia to become pathogenic in the first place.

# **CRYPTOSPORIDIA**

# Etiology

Cryptosporidium parvum may infect animals that ingest the sporulated oocysts. These oocysts originate from infested animals but may be carried in water. Thin-walled oocysts are produced, which can rupture in the intestine and produce autoinfection. The organism infests the brush border of small intestinal epithelial cells and causes diarrhea.

. Notes in the control of the contro

#### Clinical Features

Diarrhea is the most common clinical sign in dogs and cats, although many infested cats are asymptomatic. Dogs with diarrhea are usually under 6 months of age, but a similar age predilection has not been recognized for cats.

#### Diagnosis

Diagnosis requires finding the oocysts or a positive ELISA. *C. parvum* is the smallest of the coccidians and is easy to miss on fecal examination. Examination should be performed at ×1000 magnification. Use of acid-fast stains on fecal smears and fluorescent antibody techniques improves sensitivity. It is best to submit the feces to a laboratory experienced in diagnosing cryptosporidiosis. The laboratory must be warned that the feces may contain *C. parvum*, which is potentially infective for people. The ELISA is more sensitive than fecal examination.

# Treatment/Prognosis

There are no known reliable treatments. Immunocompetent people and cattle often spontaneously eliminate the infestation, but whether small animals do so is unknown. Most young dogs with diarrhea associated with cryptosporidiosis die or are cuthanized. Many cats have asymptomatic infestations, and those with diarrhea have an unknown prognosis.

#### **GIARDIASIS**

# Etiology

Giardiasis is caused by a protozoan, Giardia sp. Animals are infected when they ingest cysts shed from infected animals, often via water. Organisms are principally found in the small intestine, where they interfere with digestion through uncertain mechanisms. In people Giardia organisms may

occasionally ascend into the bile duct and cause hepatic problems.

#### **Clinical Features**

Signs vary from mild to severe diarrhea, which may be persistent, intermittent, or self-limiting. Typically the diarrhea is "cow patty"—like, without blood or mucus; however, there is substantial variation. Some animals experience weight loss; others do not. Diarrhea caused by *Giardia* can mimic large bowel diarrhea in some patients. In cats there may be an association between shedding giardial oocysts and shedding either cryptosporidial or coccidian oocysts.

# **Diagnosis**

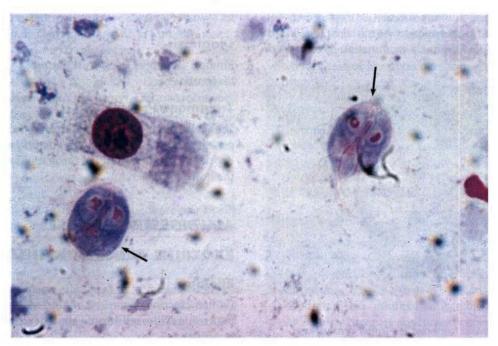

Giardiasis is diagnosed by finding motile trophozoites (Fig. 33-6) in fresh feces or duodenal washes, by finding cysts with fecal flotation techniques, or by finding giardial proteins in feces using an ELISA. Zinc sulfate solutions seem to be the best medium for demonstrating cysts (especially when centrifugal flotation is performed) because other solutions may distort them. At least three fecal examinations should be performed over the course of 7 to 10 days before discounting giardiasis. Some fecal ELISA techniques (e.g., SNAP Giardia Test, Idexx Laboratories) appear to have excellent sensitivity and are easier than centrifugal fecal flotation examinations. Washes of the duodenal lumen (performed endoscopically or surgically by instilling and then retrieving 5 to 10 ml of physiologic saline solution from the duodenal lumen) or cytologic evaluation of the duodenal mucosa

occasionally reveal *Giardia* organisms when other techniques do not.

#### **Treatment**

Because of the occasional difficulty in finding Giardia organisms (especially in animals that have had various symptomatic antidiarrheal medications), response to treatment is often the retrospective basis of diagnosis (see Table 30-7). This approach has limitations. Quinacrine is effective but no longer available. Metronidazole has few adverse effects and seems reasonably effective (approximately 85% cured after 7 days of therapy). However, clinical response to metronidazole therapy may occur in animals without giardiasis. Furazolidone (5 days of therapy) is probably as effective as metronidazole and is available as a suspension, making it easier to treat infected kittens. Albendazole (3 days of therapy in dogs, 5 days of therapy in cats) and fenbendazole (5 days of therapy in dogs or cats) are also effective, and recent data suggest that ronidazole may also be effective (see the section on tritrichomoniasis). However, none of these drugs is 100% effective, meaning that failure to respond to drug therapy does not rule out giardiasis.

There are several reasons why it can be difficult to eliminate *Giardia* spp. First, *Giardia* organisms seemingly may become resistant to some drugs. Second, immunodeficiency or concurrent host disease may make it difficult to eliminate the organism. Third, reinfection is easy because giardial cysts are rather resistant to environmental influences and relatively few are needed to reinfect a dog or person. Bathing the

**FIG 33-6**Giardia trophozoites (arrows) in a canine fecal smear that has been stained to enhance internal structures. (Magnification ×1000.) (Courtesy Dr. Tom Craig, Texas A & M University.)

patient and cleansing the environment can be very important to successful treatment in many patients. Quaternary ammonium compounds and pine tars are effective disinfectants for the premises. Fourth, sometimes other protozoal agents (e.g, *Tritrichomonas*) are mistaken for *Giardia*. Vaccination is not generally successful as a treatment modality for patients that do not respond to the aforementioned drugs.

# **Prognosis**

The prognosis for recovery is usually good, although in some cases the organisms are difficult to eradicate. Whether people may occasionally be infected with *Giardia* organisms shed from dogs is unknown.

# **TRICHOMONIASIS**

# **Etiology**

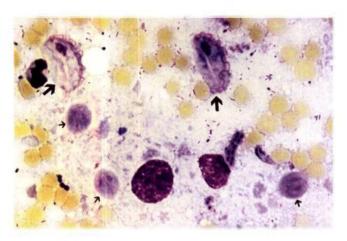

Trichomoniasis in cats appears to be caused by *Tritrichomonas foetus/suis*. Animals are probably infected by the fecaloral route.

#### **Clinical Features**

Trichomoniasis typically is associated with large bowel diarrhea, which rarely contains blood or mucus. Exotic cat breeds (e.g., Somalis, Ocicats, Bengals) are the breeds primarily affected with clinical signs. Affected cats are typically otherwise normal, although there may be anal irritation and defecation in inappropriate places. The diarrhea typically resolves spontaneously, although it may persist for months.

# Diagnosis

Diagnosis requires identifying the motile trophozoite, but live *Tritrichomonas* trophozoites can be mistaken for *Giardia* trophozoites (Fig. 33-7). Timely examination of fresh feces

#### FIG 33-7

Comparison of *Giardia* trophozoites (small arrows) and *Tritrichomonas* trophozoites (large arrows) in a smear that has been stained to enhance internal structures. Note that the *Tritrichomonas* trophozoites are larger and have one large undulating membrane. (Magnification ×1000.) (Courtesy Dr. Tom Craig, Texas A & M University.)

diluted with warm saline solution is the easiest technique, but it is insensitive. Fecal culture using the pouch technique developed for bovine venereal trichomoniasis is more sensitive.

# **Treatment/Prognosis**

Ronidazole (30 to 50 mg/kg q12h for 14 days) is the only drug currently known to safely eliminate *Tritrichomonas*, but neurologic signs have been reported with its use. If trichomoniasis is diagnosed, it is still important to look for other causes of diarrhea (e.g., *C. perfringens*, diet, *Cryptosporidium* spp.) because treatment for one of these other causes may cause resolution of the diarrhea. Most affected cats will eventually resolve the clinical signs of trichomoniasis, although diarrhea may recur if the patient undergoes stressful events (e.g., elective surgery).

#### **HETEROBILHARZIA**

# **Etiology**

Heterobilharzia americana infects dogs and establishes itself in the liver. Ova laid in the veins end up in the intestinal wall, where they elicit a granulomatous inflammation. The organism is primarily found in Gulf coast states and the southern Atlantic coast states.

#### Clinical Features

Large bowel disease is the primary sign, although the ova can be found in large and small bowel. Diarrhea, hematochezia, and weight loss are typical findings. Protein-losing enteropathy may occur, and the granulomatous reaction is associated with hypercalcemia in some dogs. Hepatic disease may be mild or severe.

#### **Diagnosis**

Finding the ova in feces or in mucosal biopsy specimens is diagnostic.

# **Treatment/Prognosis**

Fenbendazole plus praziquantel is successful in killing the parasite and the ova. However, the prognosis is seemingly dependent on the severity of the granulomatous reaction in the bowel and liver.

# MALDIGESTIVE DISEASE

# **EXOCRINE PANCREATIC INSUFFICIENCY**

#### Etiology

Canine exocrine pancreatic insufficiency (EPI) is caused by pancreatic acinar cell atrophy or destruction associated with pancreatitis.

#### **Clinical Features**

EPI is principally found in dogs and rarely in cats. Chronic small intestinal diarrhea, a ravenous appetite, and weight

loss are classic findings. Steatorrhea (i.e., slate-gray stools) is sometimes seen, and animals occasionally have weight loss without diarrhea. The diarrhea is classified as a small bowel problem (because of the weight loss and the nature of the diarrhea). Physical examination and routine clinical pathologic findings are not diagnostic. The most sensitive and specific test for canine EPI is measurement of serum trypsin-like immunoreactivity (TLI; i.e., low activity in affected dogs). Finding undetectable levels of canine pancreatic lipase immunoreactivity (cPLI) might be suggestive of EPI but is not as specific as decreased TLI. Treatment involves the administration of pancreatic enzymes with the food and manipulation of dietary fat content. The reader is referred to Chapter 40 for more information on EPI.

#### MALABSORPTIVE DISEASES

# **ANTIBIOTIC-RESPONSIVE ENTEROPATHY**

# Etiology

Antibiotic-responsive enteropathy (ARE) is a syndrome in which the duodenum or jejunum (or both) has high numbers of bacteria (i.e., usually >105 colony forming units/ml) and the host seemingly has an abnormal response to these bacteria. The abnormal host response is important, as seen by the fact that dogs with comparable numbers of bacteria in their small intestine (i.e., ≥108/ml of fasting fluid) do not have clinical disease. The bacteria may be present because of (1) an anatomic defect allowing retention of food (e.g., a partial stricture or an area of hypomotility), (2) other diseases (e.g., intestinal mucosal disease), (3) impaired host defenses (i.e., hypochlorhydria, IgA deficiency), or (4) no identifiable reason. Bacteria causing ARE are usually present in mixed culture, and they probably gain access to the alimentary tract by being swallowed (i.e., originating from the oral cavity or in the food). Any species of bacteria may be present, but Escherichia coli, enterococci, and anaerobes such as Clostridium spp. seem to be especially common. Presumably, enterocytes are damaged by deconjugation of bile acids, fatty acid hydroxylation, generation of alcohols, and potentially other mechanisms.

#### Clinical Features

ARE can be found in any dog. Clinical signs are principally diarrhea or weight loss (or both), although vomiting may also occur.

# **Diagnosis**

Currently available diagnostic tests for ARE have questionable sensitivity and specificity. Quantitative duodenal fluid cultures are difficult to obtain in most private practices and are difficult to interpret. The major value of small bowel cultures may be in patients in which the diagnosis of ARE is not in doubt but the patient is no longer responding to commonly used antibiotics, and the question is which antibiotic(s) might be effective. Serum cobalamin and folate concentra-

tions have questionable sensitivity and specificity for this disorder. Duodenal mucosal cytology and histopathology are routinely nondiagnostic for ARE. Because of these problems in diagnosing ARE, many clinicians treat and observe for response.

#### **Treatment**

Because of the difficulty in diagnosing ARE, therapy is reasonable when this disorder is suspected. Therapy consists of antibiotics and the removal of potential causes (e.g., blind or stagnant loops of intestine). Because mixed bacterial populations are expected, broad-spectrum antibiotics effective against aerobic and anaerobic bacteria are recommended. Tylosin (10 to 40 mg/kg q12h) is often effective. A combination of metronidazole (15 mg/kg q24h) and enrofloxacin (7 mg/kg q24h) also seems effective in many patients. Recent work suggests that simultaneously feeding a high-quality, highly digestible or hypoallergenic diet makes the antibiotic therapy more effective.

Occasionally, a pure culture of a specific bacteria will be found in the duodenum, such that a specific antibiotic is required. However, such cases appear to be rare. When treating dogs with suspected ARE, the clinician should wait 2 to 3 weeks before deciding that the therapy was not effective. Because there may be an underlying cause that cannot be corrected, some animals need long-term to indefinite antibiotic therapy. This may be especially true in dogs that have had repeated episodes of illness since they were a few months old. It seems as though these patients may have some genetic predisposition to ARE, probably because of a defect in host defense mechanisms. The clinician should warn the owner that the goal is typically control, not cure. Patients that have nearly constant diarrhea when not being treated may need antibiotics and dietary therapy indefinitely. Patients who have episodes every 2 to 4 months might best be treated when they relapse as opposed to having them on antibiotics constantly

# **Prognosis**

The prognosis is usually good for control of ARE, but the clinician must be concerned with possible underlying causes.

#### **DIETARY-RESPONSIVE DISEASE**

# **Etiology**

Dietary-responsive disease is an all-inclusive term that includes dietary allergy (a hyperimmune response to a dietary antigen) and dietary intolerance (a nonimmune-mediated response to a dietary substance). From a clinical standpoint, there is minimal value in distinguishing between the two unless there are concurrent cutaneous signs of allergic disease.

#### Clinical Features

Affected patients may have vomiting and/or diarrhea (large and/or small bowel) as well as allergic skin disease.

# Diagnosis

Diagnosis consists of showing response to feeding an elimination diet that is appropriate for the patient (see the discussion of dietary management in Chapter 30). There is typically minimal value in distinguishing between allergy and intolerance. Tests for IgE antibodies in the patient's blood to specific antigens are not as valuable as seeing the response to an elimination diet. The diet must be carefully chosen; it must consist of nonallergenic substances or foods to which the patient has not previously been exposed. Most animals respond to an appropriate diet within 3 weeks, although some take longer.

#### **Treatment**

Most patients that respond can simply be fed the diet to which they responded in the dietary trial (assuming that it is balanced). Rare patients develop allergies to the elimination diet and require different elimination diets to be fed on rotating 2- to 3-week cycles.

# **Prognosis**

The prognosis is usually good.

# SMALL INTESTINAL INFLAMMATORY BOWEL DISEASE

#### Clinical Features

IBD involves *idiopathic* intestinal inflammation. IBD can affect any portion of the canine or feline intestine. Although the cause of IBD is unknown, it is speculated to involve an exaggerated or inappropriate response by the immune system to bacterial and/or dietary antigens as at least part of the mechanism. The clinical and histologic features of IBD can closely resemble those of alimentary lymphoma (see p. 467). Lymphocytic-plasmacytic enteritis (LPE) is the most commonly diagnosed form of canine and feline IBD. Chronic small intestinal diarrhea is common, but some patients have weight loss with normal stools. If the duodenum is severely affected, vomiting may be the major sign, and diarrhea can be either mild or absent. Protein-losing enteropathy can occur with the more severe forms.

Eosinophilic gastroenterocolitis (EGE) is usually an allergic reaction to dietary substances (e.g., beef, milk) and as such is not IBD. However, the clinical signs do not always respond to dietary change and may represent true IBD in some dogs. It is less common than LPE. Some cats have eosinophilic enteritis as part of a hypereosinophilic syndrome (HES). The cause of feline HES is unknown, but immune-mediated and neoplastic mechanisms may be responsible. Less severely affected cats without HES seem to have a condition similar to canine EGE.

#### Diagnosis

Because IBD is *idiopathic* intestinal inflammation, it is a diagnosis of exclusion; it is not just a histologic diagnosis. No physical examination, historic, clinical pathology, imaging, or histologic findings are diagnostic of IBD. Diag-

nosis requires elimination of known causes of diarrhea plus histology showing mucosal inflammatory infiltrates, architectural changes (e.g., villus atrophy, crypt changes), and/or epithelial changes. Mucosal cytologic evaluation is unreliable for diagnosing lymphocytic inflammation because lymphocytes and plasma cells are normally present in intestinal mucosa. Histologic diagnosis of mucosal inflammation is unfortunately subjective, and biopsy samples are frequently overinterpreted. "Mild" LPE often refers to essentially normal tissue. Even descriptions of "moderate" or "severe" LPE may be dubious because of substantial inconsistency among pathologists. It can be extremely difficult to distinguish a well-differentiated lymphocytic lymphoma from severe LPE, even with full-thickness samples. Some animals with intense dietary reactions have biopsy findings that resemble lymphoma. If the biopsy specimens are of marginal quality (either from the standpoint of size or artifacts present), it is easy to mistakenly diagnose LPE instead of lymphoma if the latter is causing a secondary tissue reaction. Recent data document that biopsy of more than one site (e.g., duodenum and ileum, as opposed to just duodenum) is sometimes critical in finding inflammatory (and neoplastic) changes. Diagnosis of feline LPE is similar to that of canine LPE, but it is important to note that cats with IBD may have mild to moderate mesenteric lymphadenopathy, and such lymphadenopathy is not diagnostic of intestinal lymphoma.

Diagnosis of EGE is similar to diagnosis of LPE. Dogs with EGE may have eosinophilia and/or concurrent eosinophilic respiratory or cutaneous dietary allergies with pruritus. German Shepherd dogs seem to be overrepresented. Diagnosis of feline EGE centers on finding intestinal eosinophilic infiltrates; however, splenic, hepatic, lymph node, and bone marrow infiltrates and peripheral eosinophilia are common.

#### **Treatment**

Canine LPE treatment begins with elimination diets and antibiotics in case what appears to be IBD is actually dietary intolerance or ARE. Other therapy depends on the severity of the LPE. Somewhat more severe disease warrants metronidazole with or without high-dose corticosteroid therapy (e.g., prednisolone, 2.2 mg/kg/day or budesonide in steroid-intolerant patients). More severe disease, especially if associated with hypoalbuminemia, usually requires immunosuppressives (e.g., azathioprine or cyclosporine). Cyclosporine seems to be reasonably effective and works faster than azathioprine administered every other day; however, it is also more expensive. Elemental diets, although expensive, can be invaluable in severely emaciated or severely hypoproteinemic patients with severe inflammation as a way to feed the patient and the intestinal mucosa without causing more mucosal irritation. Failure of a dog to respond to "appropriate" therapy can be the result of inadequate therapy, owner noncompliance, or misdiagnosis (i.e., diagnosing LPE when the problem is lymphoma).

Feline LPE treatment is somewhat similar to that for canine LPE. Highly digestible elimination diets may be cura-

tive if what was thought to be IBD is actually food intolerance, and therapeutic diets should always be used if the cat will eat them. High doses of corticosteroids are typically administered early in cats because of their beneficial effects and the cat's relative resistance to iatrogenic hyperadrenocorticism. Prednisolone is preferred to prednisone in the cat, and methylprednisolone is typically more effective than prednisolone. Budesonide is primarily indicated in cats that cannot tolerate the systemic effects of steroids (e.g., those with diabetes mellitus). Low-dose metronidazole (10 to 15 mg/kg administered orally q12h), either alone or in combination with corticosteroids and diet, may also be effective. Azathioprine is not used in cats; instead, chlorambucil is used for cats with biopsy-proven, severe LPE that does not respond to other therapy (see Chapter 79) or for cats with well-differentiated lymphoma. Enteral or parenteral nutritional supplementation may be useful in emaciated cats (see Chapter 30). Parenteral administration of cobalamin to cats with severely decreased serum concentrations may aid or be necessary for remission of diarrhea. If the cat responds to this therapy, the elimination diet should be continued while the medications are gradually tapered one at a time.

Canine EGE treatment should focus on a strict hypoallergenic diet (e.g., fish and potato, turkey and potato). Partially hydrolyzed diets may also be helpful, but they are not a panacea for all GI dietary allergies/intolerances. It is important to determine what the dog was fed previously when selecting the dietary therapy. If signs do not resolve with dietary therapy, the addition of corticosteroid therapy is usually curative. Animals usually respond better to elimination diets than to corticosteroids. Sometimes, an animal initially responds to dietary management but relapses while still eating this diet because it becomes allergic to one of the ingredients. This situation necessitates administration of another elimination diet. In some animals that are very prone to developing such intolerances, switching back and forth from one elimination diet to another at 2-week intervals helps to prevent this relapse from happening. (See Chapter 30 for more information on these therapies.)

Feline EGE associated with hypereosinophilic syndrome usually requires high-dose corticosteroid therapy (i.e., prednisolone, 4.4 to 6.6 mg/kg/day); response is often poor. Cats with eosinophilic enteritis not caused by HES often respond favorably to elimination diets plus corticosteroid therapy.

If the dog or cat responds clinically, then the therapy should be continued without change for another 2 to 4 weeks to ensure that the clinical improvement is the result of the therapy and not an unrelated transient improvement. Once the clinician is convinced that the prescribed therapy is responsible for the improvement seen, the animal should be slowly weaned from the drugs, starting with those that have the greatest potential for adverse effects. If antiinflammatory or immunosuppressive therapy was initially required, the clinician should attempt to maintain the pet on every-other-day corticosteroid and azathioprine therapy. If that regimen is successful, then the lowest effective dose of each should be slowly determined. Only one change should be made at a

time, and the dose should not be decreased more frequently than once every 2 to 3 weeks, if possible. If a homemade diet was used initially, the clinician should seek to transition the patient to a complete, balanced commercial elimination diet. Dietary and antibiotic therapy are usually the last to be altered. There is no obvious benefit to rebiopsying patients that are clinically improving.

# **Prognosis**

The prognosis for dogs and cats with LPE is often good, if therapy is begun before the patient is emaciated. Severe hypoalbuminemia and a very poor body condition are thought to be suggestive that the patient may have more difficulty responding. A markedly low serum cobalamin concentration in the dog might be a poor prognostic sign, but that is uncertain. Many animals will need to be on a special diet for the rest of their lives. Many with moderate to severe disease will need prolonged medical therapy, which should be tapered cautiously. Iatrogenic Cushing's syndrome should be avoided. Severely affected animals may initially benefit from enteral or parenteral nutritional therapy. Although the relationship is unclear, LPE has been suggested to be a potentially prelymphomatous lesion (see p. 460 for immunoproliferative enteropathy in Basenjis); however, this is uncertain. If a dog or cat with a prior diagnosis of LPE is later diagnosed as having lymphoma, it may be just as likely that either the initial diagnosis of IBD was wrong (i.e., the patient had lymphoma) or that the lymphoma developed independently of the IBD.

# LARGE INTESTINAL INFLAMMATORY BOWEL DISEASE

# Clinical Features

In the author's practice, Clostridium colitis, parasites, dietary intolerance, and fiber-responsive diarrhea are responsible for most cases referred and previously diagnosed as having "intractable" large bowel "IBD." Canine lymphocytic-plasmacytic colitis (LPC) typically causes large bowel diarrhea (i.e., soft stools with or without blood or mucus; no appreciable weight loss). In general, affected dogs are fundamentally healthy except for soft stools. In cats hematochezia is the most common clinical sign, and diarrhea is the second most common sign. Feline LPC may occur by itself or concurrently with LPE, whereas canine large bowel IBD seems to be infrequently associated with small bowel IBD.

# Diagnosis

Diagnosis (i.e., excluding other causes and finding mucosal histologic changes) is similar to that for small bowel IBD. In particular, *Tritrichomonas* can cause substantial mononuclear infiltrates into feline colonic mucosa.

# Treatment

Steroids, metronidazole, sulfasalazine (Azulfidine), mesalamine, or olsalazine may be used in dogs with moderate to severe LPC. Corticosteroids and/or metronidazole may be

effective by themselves and/or allow lower doses of sulfasalazine to be successful. Hypoallergenic and fiber-enriched diets are often very helpful. It is critical to eliminate colonic fungal infections before begining immunosuppressive therapy.

High-fiber and hypoallergenic diets are also often beneficial in cats; in fact, most "intractable" feline LPC cases seen in the author's practice are ultimately determined to be related to diet. Most cats with LPC respond well to prednisolone and/or metronidazole, and sulfasalazine is rarely needed.

# **Prognosis**

The prognosis for patients with colonic IBD tends to be better than for small bowel IBD.

# GRANULOMATOUS ENTERITIS/ GASTRITIS

Canine granulomatous enteritis/gastritis is uncommon, and it can be diagnosed only histopathologically. The clinician should search diligently for an etiology (e.g., fungal). Clinical signs are similar to those of other forms of IBD. Although compared to Crohn's disease in people, the two are dissimilar. If the disease is localized, surgical resection should be considered if the clinician is sure that there is not a systemic cause (e.g., fungal). If it is diffuse, corticosteroids, metronidazole, antibiotics, azathioprine, and dietary therapy should be considered. Too few cases have been described and treated to allow generalizations. The prognosis is poor.

Feline granulomatous enteritis is a rare type of IBD that causes weight loss, protein-losing enteropathy, and perhaps diarrhea; it also requires histopathologic confirmation. Affected cats seem to respond to high-dose corticosteroid therapy, but attempts to reduce the dose of glucocorticoids may cause recurrence of clinical signs. The prognosis is guarded.

# IMMUNOPROLIFERATIVE ENTEROPATHY IN BASENJIS

#### Etiology

Immunoproliferative enteropathy in Basenjis is an intense lymphocytic-plasmacytic small intestinal infiltrate often associated with villous clubbing, mild lacteal dilation, gastric rugal hypertrophy, lymphocytic gastritis, and/or gastric mucosal atrophy. It probably has a genetic basis or predisposition, and intestinal bacteria may play an important role.

#### **Clinical Features**

The disease tends to be a severe form of LPE that waxes and wanes, particularly as the animal is stressed (e.g., traveling, disease). Weight loss, small intestinal diarrhea, vomiting, and/or anorexia are commonly seen. Most affected Basenjis start showing clinical signs by 3 to 4 years of age.

#### Diagnosis

Marked hypoalbuminemia and hyperglobulinemia are common, especially in advanced cases. The early stages of the disease resemble many other intestinal disorders. In advanced cases the clinical signs are so suggestive that a presumptive diagnosis is often made without biopsy.

However, because other diseases (e.g., lymphoma, histoplasmosis) may mimic immunoproliferative enteropathy, alimentary tract biopsy is needed before aggressive immunosuppressive therapy is begun.

#### **Treatment**

Therapy may include highly digestible, elimination, or elemental diets; antibiotics for ARE (see p. 457); high-dose corticosteroids; metronidazole; and azathioprine. Response to therapy is variable, and affected dogs that respond are at risk for relapse, especially if stressed.

Although a genetic basis is suspected, not enough is known to be able to confidently recommend a breeding program. Performing biopsy of the intestines of asymptomatic dogs to identify animals in which the disease will develop is dubious because clinically normal Basenjis may have lesions similar to those of dogs with diarrhea and weight loss, although the changes tend to be milder.

# **Prognosis**

Many affected animals die 2 to 3 years after diagnosis. The prognosis is poor for recovery, but some dogs can be maintained for prolonged periods of time with careful monitoring and care. In a few dogs lymphoma later develops.

#### ENTEROPATHY IN CHINESE SHAR-PEIS

#### Etiology

Chinese Shar-Peis have a poorly characterized enteropathy that may be unique to them or may be a severe form of IBD. Chinese Shar-Peis have immune system abnormalities that may predispose them to exaggerated inflammatory reactions.

#### Clinical Features

Diarrhea and/or weight loss (i.e., small intestinal dysfunction) are the main clinical signs.

## Diagnosis

Small intestinal biopsy is necessary for diagnosis. Eosinophilic and lymphocytic-plasmacytic intestinal infiltrates are typically found. Serum cobalamin concentrations are often quite low.

# **Treatment**

The animal is treated for IBD (i.e., elimination diets and immunosuppressive drugs) and ARE.

# **Prognosis**

Affected Chinese Shar-Peis have a guarded prognosis.

# PROTEIN-LOSING ENTEROPATHY

# CAUSES OF PROTEIN-LOSING ENTEROPATHY

Any intestinal disease that produces sufficient inflammation, infiltration, congestion, or bleeding can produce a protein-

losing enteropathy (PLE; or gastropathy if it affects the stomach; see Box 28-10). IBD and alimentary tract lymphoma have been suggested as particularly common causes in adult dogs, whereas hookworms and chronic intussusception are common causes in very young dogs. When IBD is responsible, it is usually a severe form of LPE, although EGE or granulomatous disease may be responsible. Immunoproliferative enteritis of Basenjis, GI ulceration/erosion, and bleeding tumors may also produce PLE. Lymphangiectasia appears to be more common (in dogs) than was once thought; the problem is that it can be difficult to diagnose. Cats infrequently have PLE, but when it occurs, it is usually caused by LPE or lymphoma. Therapy should be directed at managing the underlying cause.

#### INTESTINAL LYMPHANGIECTASIA

# **Etiology**

Intestinal lymphangiectasia (IL) is a disorder of the intestinal lymphatic system of dogs. Lymphatic obstruction causes dilation and rupture of intestinal lacteals with subsequent leakage of lymphatic contents (i.e., protein, lymphocytes, and chylomicrons) into the intestinal submucosa, lamina propria, and lumen. Although these proteins may be digested and resorbed, excessive loss exceeds the intestine's ability to resorb them, thus resulting in hypoalbuminemia. Leakage of lymphatic fat into the intestinal wall may cause granuloma formation, which exacerbates lymphatic obstruction. Not reported in cats, the condition has many potential causes in dogs (e.g., lymphatic obstruction, pericarditis, infiltrative mesenteric lymph node disease, infiltrative intestinal mucosal disease, congenital malformations). Most cases of symptomatic IL are idiopathic.

# **Clinical Features**

Yorkshire Terriers, Soft Coated Wheaten Terriers, and Lundehunds appear to be at higher risk than other breeds. Soft Coated Wheaten Terriers also have an unusually high incidence of protein-losing nephropathy. The first sign of disease caused by IL may be transudative ascites. Diarrhea is inconsistent and may occur early or late in the course of the disease, if at all. Intestinal lipogranulomas (i.e., white nodules in the intestinal serosa or mesentery) are sometimes found at surgery. They are probably secondary to IL (i.e., fat leaking out of dilated lymphatic vessels), but they might worsen existing IL by further obstructing lymphatics.

# Diagnosis

Clinical pathologic evaluation is not diagnostic, but hypoalbuminemia and hypocholesterolemia are expected. Although panhypoproteinemia is classically attributed to PLE, animals that were initially hyperglobulinemic may lose most of their serum proteins and still have normal serum globulin concentrations. Lymphopenia is common but inconsistent. Diagnosis requires intestinal histopathology. Feeding the animal fat the night before the biopsy seems to make lesions more obvious, and classic mucosal lesions may be seen endoscopically (Fig. 33-8). Endoscopic biopsies are often diagnos-

FIG 33-8
Endoscopic image of the duodenum of a dog with lymphangiectasia. The large white "dots" are dilated lacteals in the tips of the villi.

tic if done appropriately, but surgical biopsies are sometimes required. If full-thickness surgical biopsies are performed, serosal patch grafting and nonabsorbable suture material may decrease the risk of dehiscence. IL may be localized to one area of the intestines (e.g., ileum).

#### **Treatment**

The underlying cause of IL is rarely determined, necessitating reliance on symptomatic therapy. An ultra–low-fat diet essentially devoid of long-chain fatty acids helps to prevent further intestinal lacteal engorgement and subsequent protein loss. Prednisolone (1.1 to 2.2 mg/kg/day) or azathioprine (2.2 mg/kg q48h) or cyclosporine (3-5 mg/kg q24h to q12h) sometimes lessens inflammation around the lipogranulomas and improves lymphatic flow.

Monitoring serum albumin concentration may be the best way of assessing response to therapy. If the animal improves with dietary therapy, it should probably be fed that diet indefinitely. Azathioprine or cyclosporine therapy might help solidify response to dietary therapy and maintain remission.

# **Prognosis**

The prognosis is variable, but most dogs respond well to ultra-low-fat diets, although some require prednisolone in addition to the diet. A few dogs die despite dietary and prednisolone therapy.

# PROTEIN-LOSING ENTEROPATHY IN SOFT-COATED WHEATEN TERRIERS

# Etiology

Soft Coated Wheaten Terriers (SCWTs) have a predisposition to PLE and protein-losing nephropathy. The cause is

uncertain, although food hypersensitivity has been reported to be present in some affected dogs.

# **Clinical Features**

Individual dogs may have PLE or protein-losing nephropathy (or both). Typical clinical signs may include vomiting, diarrhea, weight loss, and ascites. Affected dogs are often middle aged when diagnosed.

# Diagnosis

Panhypoproteinemia and hypocholesterolemia are common, as with any PLE. Histopathology of intestinal mucosa may reveal lymphangiectasia, lymphangitis, or supposedly IBD.

# **Treatment/Prognosis**

Treatment is typically as for lymphangiectasia and/or IBD. The prognosis appears guarded to poor for clinically ill animals, with most dying within a year of diagnosis.

# **FUNCTIONAL INTESTINAL DISEASE**

#### IRRITABLE BOWEL SYNDROME

# Etiology

Irritable bowel syndrome (IBS) in people is characterized by diarrhea, constipation, and/or cramping (usually of the large intestines) in which an organic lesion cannot be identified. It is an idiopathic large bowel disease in which all known causes of diarrhea have been eliminated and a "functional" disorder is presumed. IBS in dogs is different and primarily involves an idiopathic, chronic large bowel diarrhea in which parasitic, dietary, bacterial, and inflammatory causes have been eliminated. There are probably various causes of this syndrome in dogs.

#### **Clinical Features**

Chronic large bowel diarrhea is the principal sign. Fecal mucus is common, blood in the feces is infrequent, and weight loss is very rare. Some dogs with IBS are small breeds that are heavily imprinted on a single family member. Clinical signs may develop following separation of the dog from the favored person. Other dogs with IBS are nervous and high-strung (e.g., police or guard dogs, especially German Shepherd Dogs). Some dogs have no apparent initiating cause.

# Diagnosis

Diagnosis consists of eliminating known causes by physical examination, clinical pathologic data, fecal analysis, colonoscopy/biopsy, and appropriately performed therapeutic trials.

## **Treatment**

Treatment with fiber-supplemented diets (i.e., ≥7% to 9% fiber on a dry matter basis) is often helpful (see p. 398). Many animals must receive fiber chronically to prevent relapse.

Anticholinergics occasionally are useful (e.g., propantheline, 0.25 mg/kg; or dicyclomine, 0.15 mg/kg up to q8h, as needed).

# **Prognosis**

The prognosis is good; in most animals the signs are controlled by diet or medical management.

# INTESTINAL OBSTRUCTION

# SIMPLE INTESTINAL OBSTRUCTION

# Etiology

Simple intestinal obstruction (i.e., the intestinal lumen is obstructed but without peritoneal leakage, severe venous occlusion, or bowel devitalization) is usually caused by foreign objects. Infiltrative disease and intussusception may also be responsible.

# **Clinical Features**

Simple intestinal obstructions usually cause vomiting with or without anorexia, depression, or diarrhea. Abdominal pain is uncommon. The more orad the obstruction is, the more frequent and severe the vomiting tends to be. If the intestine becomes devitalized and septic peritonitis results, the obstruction becomes complicated and the animal may be presented in a moribund state or in septic shock (systemic inflammatory response syndrome, or SIRS).

# **Diagnosis**

Abdominal palpation, plain abdominal radiographs, or ultrasonographic imaging can be diagnostic if they reveal a foreign object, mass, or obvious obstructive ileus (see Fig. 29-5, A). Masses or dilated intestinal loops may be found with either technique. Abdominal ultrasonography tends to be the most sensitive technique (unless the intestines are filled with gas) and can reveal dilated or thickened intestinal loops that are not obvious on radiographs (e.g., poor serosal contrast caused by abdominal fluid or lack of abdominal fat) or palpation. If it is difficult to distinguish obstruction from physiologic ileus, abdominal contrast radiographs may be considered. Many intestinal foreign bodies cause hypochloremic, hypokalemic metabolic alkalosis, a metabolic change that is supposedly suggestive of gastric outflow obstruction.

Finding a foreign object is usually sufficient to establish a diagnosis. If an abdominal mass or an obvious obstructive ileus is found, a presumptive diagnosis of obstruction is made, and ultrasonography or exploratory surgery should be planned. Aspirate cytologic evaluation of masses may be used to diagnose some diseases (e.g., lymphoma) before surgery.

#### **Treatment**

Once intestinal obstruction is diagnosed, the clinician should perform routine preanesthetic laboratory tests (serum electrolyte and acid-base abnormalities are common in vomiting animals), stabilize the animal, and promptly proceed to surgery. Vomiting of gastric origin classically produces a hypokalemic, hypochloremic metabolic alkalosis and paradoxical aciduria, whereas vomiting caused by intestinal obstruction may produce metabolic acidosis and varying degrees of hypokalemia. However, these changes cannot be predicted even when the cause of the vomiting is known, making serum electrolyte and acid-base determinations important in therapy planning.

# **Prognosis**

If septic peritonitis is absent and massive intestinal resection is not necessary, the prognosis is usually good.

# INCARCERATED INTESTINAL OBSTRUCTION

# **Etiology**

Incarcerated intestinal obstruction involves a loop of intestine trapped or "strangulated" as it passes through a hernia (e.g., abdominal wall, mesenteric) or similar rent. The entrapped intestinal loop quickly dilates, accumulating fluid in which bacteria flourish and release endotoxins. SIRS occurs rapidly. This is a true surgical emergency, and animals deteriorate quickly if the entrapped loop is not removed.

## **Clinical Features**

Dogs and cats with incarcerated intestinal obstruction typically have acute vomiting, abdominal pain, and progressive depression. Palpation of the entrapped loop often causes severe pain and occasionally vomiting. On physical examination, "muddy" mucous membranes and tachycardia may be noted, suggesting endotoxic shock.

#### Diagnosis

A presumptive diagnosis is made by finding a distended, painful intestinal loop, especially if the loop is contained within a hernia. Radiographically, a markedly dilated segment of intestine is detected (Fig. 33-9) that is sometimes obviously outside the peritoneal cavity. Otherwise, an obviously strangulated loop of intestine will be found at exploratory surgery.

# Treatment

Immediate surgery and aggressive therapy for endotoxic shock are indicated. Devitalized bowel should be resected, with care taken to avoid spillage of septic contents into the abdomen.

# **Prognosis**

The prognosis is guarded. Rapid recognition and prompt surgery are necessary to prevent mortality.

# MESENTERIC TORSION/VOLVULUS

# Etiology

In mesenteric torsion/volvulus, the intestines twist about the root of the mesentery, causing severe vascular compromise.

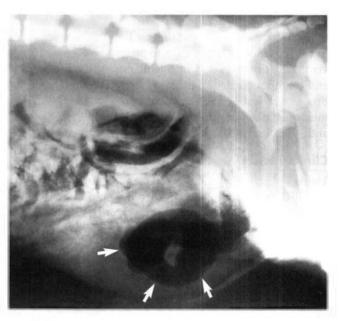

FIG 33-9

Lateral abdominal radiograph of a dog with a ruptured prepubic tendon and incarcerated intestinal obstruction. Note the dilated section of intestine in the area of the hernia (arrows). (From Allen D, editor: Small animal medicine, Philadelphia, 1991, JB Lippincott.)

Much of the intestine is typically devitalized by the time surgery is performed.

# **Clinical Features**

This uncommon cause of intestinal obstruction principally occurs in large dogs (especially German Shepherd Dogs). Mesenteric torsion is denoted by an acute onset of severe nausea, retching, vomiting, abdominal pain, and depression. Bloody diarrhea may or may not occur. Abdominal distention is not as evident as it is in animals with gastric dilation/volvulus (GDV).

# Diagnosis

Abdominal radiographs are often diagnostic and typically show widespread, uniform ileus (see Fig. 29-6).

#### **Treatment**

Immediate surgery is necessary. The intestines must be properly repositioned, and devitalized bowel must be resected.

# **Prognosis**

The prognosis is extremely poor; most animals die despite heroic efforts. Animals that live may develop short bowel syndrome if massive intestinal resection is necessary.

#### LINEAR FOREIGN OBJECTS

#### Etiology

Numerous objects can assume a linear configuration in the alimentary tract (e.g., string, thread, nylon stockings, cloth).

The foreign object lodges or fixes at one point (e.g., the base of the tongue, pylorus), and the rest trails off into the intestines. The small intestine seeks to propel the object aborally via peristaltic waves and in this manner gathers around it and becomes pleated. As the intestines continue trying to propel it aborally, the linear object cuts or "saws" into the intestines, often perforating them at multiple sites on the antimesenteric border. Fatal peritonitis can result.

## **Clinical Features**

Linear foreign objects appear to be more frequent in cats than in dogs. Vomiting food, bile, and/or phlegm is common, but some animals show only anorexia or depression. A few (especially dogs with chronic linear foreign bodies) can be relatively asymptomatic for days to weeks while the foreign body continues to embed itself in the intestines.

# Diagnosis

The history may be suggestive of a linear foreign body (e.g., the cat was playing with cloth or string). Bunched, painful intestines are occasionally detected by abdominal palpation. The object is sometimes seen lodged at the base of the tongue; however, failure to find a foreign object at the base of the tongue does not eliminate linear foreign body as a diagnosis. Even when such objects lodge under the tongue, they can be very difficult to find despite a careful, thorough oral examination; some become embedded in the frenulum. If necessary, chemical restraint (e.g., ketamine, 2 mg/kg administered intravenously) should be used to allow adequate oral examination.

Foreign objects lodged at the pylorus and trailing off into the duodenum must be diagnosed by abdominal palpation, imaging, or endoscopy. The objects themselves are infrequently seen radiographically and only rarely produce dilated intestinal loops suggesting anatomic ileus; the proximity to the stomach and the pleating of the intestines around the object usually prevents the intestines from dilating. Plain radiographs may reveal small gas bubbles in the intestines, especially in the region of the duodenum, and obvious intestinal pleating may occasionally be seen (Fig. 33-10). If contrast radiographs are performed, they typically reveal a pleated or bunched intestinal pattern, which is diagnostic of linear foreign body. Finally, these objects are sometimes seen endoscopically lodged at the pylorus.

## **Treatment**

Abdominal surgery is often needed to remove linear foreign objects. However, if the animal is otherwise healthy, if the linear foreign object has been present for only 1 or 2 days, and if it is fixed under the tongue, the object may be cut loose to see if it will now pass through the intestines without further problem. Surgery is indicated if the animal does not feel better 12 to 24 hours after the object is cut free from its point of fixation.

If there is doubt as to the length of time that the object has been present, or if it is fixed at the pylorus, surgery is usually a safer therapeutic approach. Endoscopic removal occasionally succeeds, but the clinician must be careful because it is easy to rupture devitalized intestine and cause peritonitis. If the clinician can pass the tip of the endoscope to near the aborad end of the object and pull it out by grabbing the aborad end, surgery is sometimes unnecessary.

# **Prognosis**

The prognosis is usually good if severe septic peritonitis is absent and massive intestinal resection is unnecessary. If a linear foreign object has been present a long time, it may embed itself in the intestinal mucosa, making intestinal resection necessary. When massive intestinal resection is necessary, short bowel syndrome can result; this condition has a guarded to poor prognosis.

#### INTUSSUSCEPTION

# **Etiology**

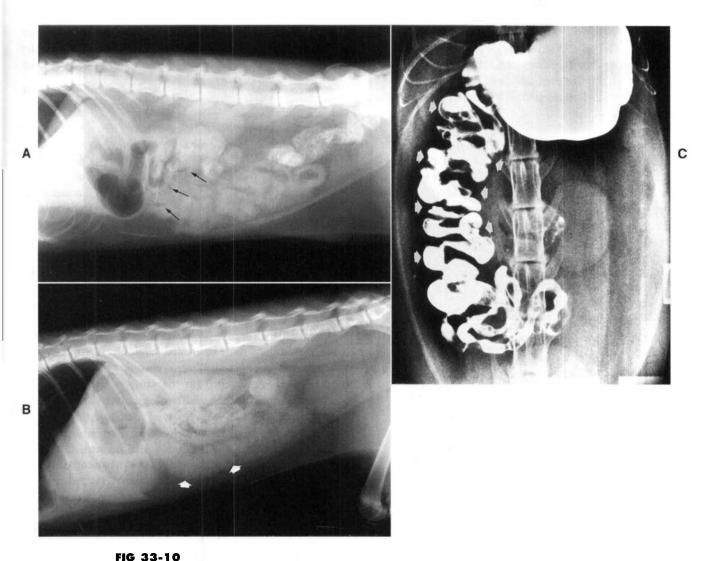

Intussusception is a telescoping of one intestinal segment (the intussusceptum) into an adjacent segment (the intussuscipiens). It may occur anywhere in the alimentary tract, but ileocolic intussusceptions (i.e., the ileum entering the colon) seem more common. Ileocolic intussusceptions seem to be associated with active enteritis (especially in young animals), which ostensibly disrupts normal motility and promotes the smaller ileum to intussuscept into the larger diameter colon. However, ileocolic intussusception may occur in animals with acute renal failure, leptospirosis, prior intestinal surgery, and other problems.

# **Clinical Features**

Acute ileocolic intussusception causes obstruction of the intestinal lumen and congestion of the intussusceptum's mucosa. Scant bloody diarrhea, vomiting, abdominal pain, and a palpable abdominal mass are common. Chronic ileocolic intussusceptions typically produce less vomiting, abdominal pain, and hematochezia. These animals often have intractable diarrhea and hypoalbuminemia because of protein loss from the congested mucosa. PLE in a young dog without hookworms or a puppy that seems to be having an unexpectedly long recovery from parvoviral enteritis should prompt suspicion of chronic intussusception. Acute jejunojejunal intussusceptions usually do not cause hematochezia. Mucosal congestion can be more severe than that in ileocolic intussusception; intestinal devitalization eventually occurs, and bacteria and their toxins gain access to the peritoneal cavity.

# **Diagnosis**

Palpation of an elongated, obviously thickened intestinal loop establishes a presumptive diagnosis; however, some infiltrative diseases produce similar findings. Ileocolic intussusceptions that are short and do not extend far into the descending colon may be especially difficult to palpate because they are high up and under the rib cage. Occasional intussusceptions "slide" in and out of the colon and can be

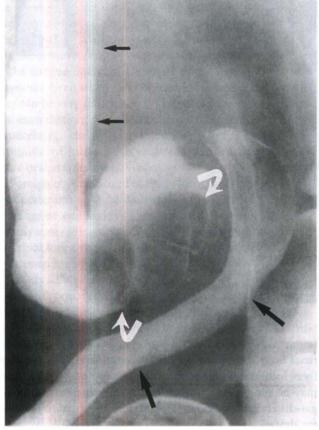

A, Plain abdominal radiograph of a cat with a linear foreign body lodged at the pylorus. Note the small gas bubbles in the mass of intestines (arrows). B, Plain abdominal radiograph of a cat with a linear foreign body. Note the obviously pleated small bowel (arrows). C, Contrast radiograph of a cat with a linear foreign body. Note the pleated, bunched pattern of intestines (arrows). (A from Allen D, editor: Small animal medicine, Philadelphia, 1991, JB Lippincott.)

missed during abdominal palpation. If the intussusception protrudes as far as the rectum, it may resemble a rectal prolapse. Therefore if tissue is protruding from the rectum, the clinician should perform a careful rectal palpation to ascertain that a fornix exists (i.e., it is a rectal prolapse) as opposed to an intussusception (in which a fornix cannot be found).

Plain abdominal radiographs infrequently allow the diagnosis of ileocolic intussusceptions because they usually cause minimal intestinal gas accumulation. A properly performed barium contrast enema may reveal a characteristic colonic filling defect caused by the intussuscepted ileum (Fig. 33-11). Abdominal ultrasonography is quick and reasonably sensitive and specific for detecting intussusceptions (see Fig. 29-8, B). Colonoscopy can be definitive if the intussuscepted intestine is seen extending into the colon (Fig. 33-12). Jejunojejunal intussusceptions may be easier to palpate because of their location. Furthermore, plain abdominal radiographs may be more likely to demonstrate obstructive ileus (i.e., gas-distended bowel loops) because the obstruction is not so far aborad.

A reason for the intussusception (e.g., parasites, mass, enteritis) should always be sought. Fecal examination for parasites and evaluation of full-thickness intestinal biopsy specimens obtained at the time of surgical correction of the intussusception should be performed. In particular, the tip of the intussuscepted bowel (i.e., the intussusceptum) should be examined for a mass lesion (e.g., tumor), which could have served as a focus and allowed the intussusception to occur. Additional diagnostic tests may be warranted depending on the history, physical examination findings, and results of clinical pathologic evaluation.

#### FIG 33-11

B

**A,** Lateral radiograph taken during a barium enema of a dog. Contrast medium outlines the end of a large ileocolic intussusception (thin arrows). Note that barium does not fill up the normally positioned colonic lumen because of a long filling defect (large arrows). **B,** Spot radiograph taken during a barium enema of a dog. The colon is descending on the left (short arrows), and the ileum (long arrows) is entering the colon. There is an area in which barium is displaced, representing an intussuscepted cecum (curved arrows). (**A** courtesy Dr. Alice Wolf, Texas A & M University.)

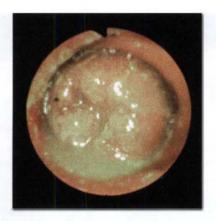

FIG 33-12

Endoscopic view of the ascending colon of a dog with an ileocolic intussusception. Note the large, "hot dog"-like mass in the colonic lumen, which is the intussusception.

#### **Treatment**

Intussusceptions must be treated surgically. Acute ones may be reduced or resected, whereas chronic ones usually must be resected. Recurrence (in the same or a different site) is reasonably common. Surgical plication helps prevent recurrence.

# **Prognosis**

The prognosis is often good if septic peritonitis has not occurred and the intestines do not reintussuscept.

# MISCELLANEOUS INTESTINAL DISEASES

# SHORT BOWEL SYNDROME

# Etiology

Short bowel syndrome occurs when extensive resection of intestines results in the need for special nutritional therapy until the intestines are able to adapt. This is typically an iatrogenic disorder caused by resection of more than 75% to 90% of the small intestine. The remaining intestine is unable to adequately digest and absorb nutrients. Large numbers of bacteria may reach the upper small intestines, especially if the ileocolic valve is removed. However, not all animals with substantial small intestinal resections develop this syndrome. Dogs and cats seem better able than people to tolerate loss of a large percentage of small intestine.

## **Clinical Features**

Affected animals usually have severe weight loss and intractable diarrhea (typically without mucus or blood), which often occurs shortly after eating. Undigested food particles are often seen in the feces.

#### **Diagnosis**

A history of substantial resection in conjunction with the clinical signs is sufficient for diagnosis. It is wise to deter-

mine how much small intestine is left by performing contrast radiographs; estimates made at surgery can be surprisingly inaccurate.

#### **Treatment**

The best treatment is prevention. One should avoid massive resections if at all possible, even if it means doing a "second look" surgery 24 to 48 hours later. If massive resection occurs and the animal cannot maintain its body weight with oral feedings alone, total parenteral nutrition is needed until intestinal adaptation has occurred and treatments have become effective in controlling clinical signs. It is important to continue to feed the animal orally to stimulate intestinal mucosal hypertrophy. The diet should be highly digestible (e.g., low-fat cottage cheese, potato) and should be fed in small amounts, at least three to four times per day. Opiate antidiarrheals (e.g., loperamide), and H2-receptor antagonists may be useful in lessening diarrhea and decreasing gastric hypersecretion. Antibiotics might be needed to control the large bacterial populations now present in the small intestine (pp. 409-410).

## **Prognosis**

If intestinal adaptation occurs, the animal may eventually be fed a near-normal diet. However, some animals will never be able to resume regular diets, and others die despite all efforts. Animals that are initially malnourished seem to have a worse prognosis than those that are well nourished. Some dogs and cats do better than one would intuitively expect them to do, despite the loss of approximately 85% of the small intestines.

#### NEOPLASMS OF THE SMALL INTESTINE

## **ALIMENTARY LYMPHOMA**

#### Etiology

Lymphoma is a neoplastic proliferation of lymphocytes (see Chapter 80) that could also be placed in the section on malabsorptive diseases. It may be caused by FeLV in cats, but the etiology in dogs is unknown. LPE has been suggested to be prelymphomatous in some animals, but the frequency of malignant transformation of LPE to lymphoma is unknown. Lymphoma often affects the intestines, although extraintestinal forms (e.g., lymph nodes, liver, spleen) are more common in dogs (see Chapter 80). Alimentary lymphoma appears to be more common in cats than in dogs.

#### **Clinical Features**

Chronic, progressive weight loss, anorexia, small intestinal diarrhea, and/or vomiting may occur. Alimentary lymphoma may cause nodules, masses, diffuse intestinal thickening resulting from infiltrative disease (see Fig. 29-9), dilated sections of intestine that are not obstructed, and/or focal constrictions. It may also be present in grossly normal-appearing intestine; PLE may also occur. Mesenteric lymph-

adenopathy (i.e., enlargement) is typical but not invariable, and it is important to note that IBD can cause mild to moderate mesenteric lymphadenopathy. Extraintestinal abnormalities (e.g., peripherallymphadenopathy) are inconsistently found in dogs and cats with alimentary lymphoma.

# **Diagnosis**

Diagnosis requires demonstration of neoplastic lymphocytes, which may be obtained by fine-needle aspiration, imprint, or squash cytologic preparations. However, histopathologic evaluation of intestinal biopsy specimens is the most reliable diagnostic method. It is important to biopsy the ileum because many patients (especially cats) do not have lymphoma in the duodenum. If endoscopic biopsy samples are obtained, a poor sample or one that is not sufficiently deep may cause the erroneous diagnosis of LPE instead of lymphoma. Finding lymphocytes in the submucosa is not specific for lymphoma: Lymphocytes can be found in the submucosa of cats with IBD. However, cats with IBD generally do not have the dramatic numbers that can be found in some cases with lymphoma. Occasionally, neoplastic lymphocytes are found only in the serosal layer and fullthickness surgical biopsy specimens are necessary, but this scenario is extremely uncommon. Animals with extremely well-differentiated lymphocytic lymphoma may be impossible to distinguish from those with LPE using routine histopathology, even with multiple full-thickness biopsy samples. This seems to be a particularly important problem in cats. In such cases, diagnosis often depends on finding lymphocytes in organs where they should not be found (e. g., liver) or in performing immunohistochemical studies to determine if the lymphoid population is monoclonal. Paraneoplastic hypercalcemia occasionally occurs but is neither sensitive nor specific for lymphoma.

#### **Treatment**

Chemotherapy is of questionable value in dogs; many patients become quite ill if given aggressive chemotherapy. Cats with well-differentiated small cell lymphoma treated with prednisolone and chlorambucil may do as well as cats with IBD that receive the same therapy. Treatment protocols are outlined in Chapter 80.

# **Prognosis**

The long-term prognosis is very poor, but some cats with well-differentiated intestinal lymphoma will live years with therapy.

# INTESTINAL ADENOCARCINOMA

Intestinal adenocarcinoma is more common in dogs than in cats. It typically causes diffuse intestinal thickening or focal circumferential mass lesions. Primary clinical signs are weight loss and vomiting caused by intestinal obstruction. Diagnosis requires demonstrating neoplastic epithelial cells. Endoscopy, surgery, and ultrasound-guided fine-needle aspiration may be diagnostic. Scirrhous carcinomas have very dense fibrous connective tissue that often cannot be

adequately biopsied with fine-needle aspiration or a flexible endoscope; therefore surgery is sometimes required to obtain diagnostic biopsies. The prognosis is good if com-plete surgical excision is possible, but metastases to regional lymph nodes are common by the time of diagnosis. Postoperative adjuvant chemotherapy does not appear to be beneficial.

# INTESTINAL LEIOMYOMA/ LEIOMYOSARCOMA

Intestinal leiomyomas and leiomyosarcomas are connective tissue tumors that usually form a distinct mass and are primarily found in the small intestine and stomach of older dogs. Primary clinical signs are intestinal hemorrhage, iron deficiency anemia, and obstruction. They can also cause hypoglycemia as a paraneoplastic effect. Diagnosis requires demonstration of neoplastic cells. Evaluation of ultrasound-guided fine-needle aspirate may be diagnostic, but these tumors do not exfoliate as readily as many carcinomas or lymphomas, and biopsy is often necessary. Surgical excision may be curative if there are no metastases. Metastases make the prognosis poor, although some animals are palliated by chemotherapy.

# INFLAMMATION OF THE LARGE INTESTINE

# **ACUTE COLITIS/PROCTITIS**

# Etiology

Acute colitis has many causes (e.g., bacteria, diet, parasites). The underlying cause is seldom diagnosed because this problem tends to be self-limiting. Acute proctitis probably has similar causes but may also be secondary to passage of a rough foreign object that traumatizes the rectal mucosa.

# **Clinical Features**

Animals with acute colitis, which is more common in dogs than in cats, often feel good despite large bowel diarrhea (i.e., hematochezia, fecal mucus, tenesmus). Vomiting occurs infrequently. The major clinical signs of acute proctitis are constipation, tenesmus, hematochezia, dyschezia, and/or depression.

# Diagnosis

Rectal examination is important; animals with acute colitis may have rectal discomfort and/or hematochezia. Eliminating obvious causes (e.g., diet, parasites) and resolving the problem with symptomatic therapy allow the clinician to make a presumptive diagnosis. Colonoscopy and biopsy are definitive but seldom performed or needed unless the initial presentation is unduly severe. Rectal examination of animals with acute proctitis may reveal roughened, thick, and/or obviously ulcerated mucosa. Proctoscopy and rectal mucosal biopsy are definitive but seldom required.

#### **Treatment**

Symptomatic therapy is typically sufficient because acute proctitis and colitis are usually idiopathic. Withholding food for 24 to 36 hours lessens the severity of clinical signs. The animal should then be fed small amounts of a bland diet (e.g., cottage cheese and rice) with or without fiber. After resolution of the clinical signs, the animal may be gradually returned to its original diet. Areas of anal excoriation should be cleansed, and an antibiotic-corticosteroid ointment should be applied. Most animals recover within 1 to 3 days. For proctitis, stool softeners and broad-spectrum antimicrobial therapy effective against anaerobic bacteria may also be used.

# **Prognosis**

The prognosis for idiopathic disease is good.

# **CHRONIC COLITIS**

For a discussion of chronic colitis, see p. 459.

# INTUSSUSCEPTION/PROLAPSE OF THE LARGE INTESTINE

#### **CECOCOLIC INTUSSUSCEPTION**

# **Etiology**

Cecocolic intussusception, in which the cecum intussuscepts into the colon, is rare. The cause is unknown, although some suggest that whipworm-induced typhlitis may be responsible.

# **Clinical Features**

Primarily occurring in dogs, intussuscepted cecums can bleed to the point where some dogs become anemic. Hematochezia is the major sign. It does not lead to intestinal obstruction and infrequently causes diarrhea.

# **Diagnosis**

Cecocolic intussusception is rarely palpated during physical examination. Flexible endoscopy, ultrasonography, and contrast enema (see Fig. 33-11, *B*) usually reveal the intussusception.

#### **Treatment**

Typhlectomy is curative, and the prognosis is good.

# **RECTAL PROLAPSE**

#### Etiology

Rectal prolapse usually occurs secondary to enteritis or colitis in young animals. They begin to strain because of rectal irritation, and eventually some or all of the rectal mucosa prolapses. Mucosal exposure increases irritation and perpetuates straining, which promotes prolapse. Hence a

positive feedback cycle is initiated. Manx cats appear to be predisposed to rectal prolapse.

#### **Clinical Features**

Dogs and cats (especially juveniles) are affected. The presence of colonic or rectal mucosa extending from the anus is obvious during the physical examination.

# **Diagnosis**

The diagnosis is based on physical examination. Rectal examination is needed to differentiate rectal prolapse from an intussusception protruding from the rectum (see p. 465).

#### **Treatment**

Treatment consists of resolving the original cause of straining if possible, repositioning the rectal mucosa, and preventing additional straining/prolapse. A well-lubricated finger is used to reposition the mucosa. If it readily prolapses after being replaced, a purse-string suture in the anus is used for 1 to 3 days to hold it in position. The subsequent rectal opening must be large enough so that the animal can defecate. Occasionally, an epidural anesthetic is needed to prevent repeated prolapse. If the everted mucosa is so irritated that straining continues, retention enemas with kaolin or barium may provide relief. If a massive prolapse is present or the rectal mucosa is irreversibly damaged, resection may be necessary.

## **Prognosis**

The prognosis is usually good, but some cases tend to recur.

#### NEOPLASMS OF THE LARGE INTESTINE

## **ADENOCARCINOMA**

# Etiology

The cause of adenocarcinoma is unknown. Contrary to adenocarcinoma in people, relatively few cases of colonic adenocarcinoma in dogs have been found to arise from polyps. These tumors can extend into the lumen or be infiltrative and produce a circumferential narrowing.

#### **Clinical Features**

Principally found in dogs, colonic and rectal adenocarcinomas are more common in older animals. Hematochezia is common. Infiltrative tumors are likely to cause tenesmus and/or constipation secondary to obstruction.

# **Diagnosis**

Finding carcinoma cells is necessary for a diagnosis. Histopathologic evaluation is often preferable to cytologic analysis because epithelial dysplasia may be present in benign lesions, causing a false-positive cytologic diagnosis of carcinoma. Relatively deep biopsies obtained with rigid biopsy forceps are usually required to diagnose submucosal carcinomas and distinguish benign polyps from carcinomas because invasion of the submucosa is an important feature of rectal adenocarcinomas. Because most colonic neoplasms arise in or near the rectum, digital examination is the best screening test. Colonoscopy is required for masses farther orad. Imaging is used to detect sublumbar lymph node or pulmonary involvement (i.e., metastases).

#### **Treatment**

Complete surgical excision is curative; however, most malignancies cannot be surgically cured because of their location in the pelvic canal, extent of local invasion, and/or tendency to metastasize to regional lymph nodes.

# **Prognosis**

The prognosis for unresectable adenocarcinoma is poor. Preoperative and intraoperative radiotherapy may be palliative for some dogs with nonresectable colorectal adenocarcinomas.

#### **RECTAL POLYPS**

# **Etiology**

The cause of rectal polyps is unknown.

#### **Clinical Features**

Principally found in dogs, hematochezia (which may be considerable) and tenesmus are the primary clinical signs. Obstruction is rare.

# **Diagnosis**

Usually detected during rectal examination, some adenomatous polyps resemble sessile adenocarcinomas because they are so large that the narrow, stalklike attachment cannot be readily discerned. Occasionally, multiple small polyps may be palpated throughout one segment of the colon, usually within a few centimeters of the rectum (Fig. 33-13). Histo-

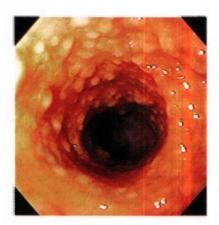

FIG 33-13

Endoscopic view of the distal colon of a dog that has multiple benign polyps. Biopsy is necessary to determine that these are not inflammatory or malignant. pathology is required for diagnosis and to distinguish polyps from malignancies.

#### **Treatment**

Complete excision via surgery or endoscopy is curative. If possible, a thorough endoscopic or imaging evaluation of the colon should be done before surgery to ensure that additional polyps are not present. If they are incompletely excised, polyps return and must be excised again. Multiple polyps within a defined area may necessitate segmental colonic mucosal resection.

# **Prognosis**

Most canine rectal and colonic polyps do not result in carcinoma *in situ*, possibly because they are diagnosed relatively sooner than colonic polyps in people. The prognosis is good.

# MISCELLANEOUS LARGE INTESTINAL DISEASES

# **PYTHIOSIS**

# **Etiology**

As discussed in Chapter 32, pythiosis is caused by *Pythium insidiosum*.

#### **Clinical Features**

Pythiosis of the large bowel usually occurs at or near the rectum. However, it can involve any area of the intestinal tract. Rectal lesions often cause partial obstruction. Fistulae may develop, resembling perianal fistulae. The dog may be presented for constipation and/or hematochezia. Animals

with advanced disease often lose weight. In rare cases there will be infarction of mucosa or vessels with subsequent ischemia. Cats are rarely affected.

# Diagnosis

Because the lesion is submucosal and very fibrotic, rigid biopsy forceps are typically necessary to obtain deep, diagnostic samples that include substantial amounts of submucosa (i.e., where the organism is found; Fig. 33-14). Special stains (e.g., Warthin-Starry) are needed to find the organism. Sometimes, the organism cannot be found, but a suggestive pyogranulomatous, eosinophilic inflammation is present. Serologic tests for antigen and antibodies are available (see Chapter 29).

# **Treatment**

Complete surgical excision is preferred. No medication has consistently been effective, although itraconazole or liposomal amphotericin B plus/minus terbenifine might be temporarily beneficial in some dogs.

# **Prognosis**

The prognosis is poor unless the lesion can be completely excised.

# PERINEAL/PERIANAL DISEASES

## **PERINEAL HERNIA**

# **Etiology**

Perineal hernia occurs when the pelvic diaphragm (i.e., coccygeus and levator ani muscles) weakens and allows the rectal canal to deviate laterally.

#### FIG 33-14

Photomicrograph of a colonic biopsy specimen. The mucosa is intact, but granulomas below the mucosa (arrows) contain fungal hyphae. These granulomas would not be found by superficial mucosal sampling. These granulomas are caused by pythiosis.

#### Clinical Features

This condition is principally found in older intact male dogs (especially Boston Terriers, Boxers, Cardigan Welsh Corgis, and Pekingeses); cats are rarely affected. Most animals present because of dyschezia, constipation, or perineal swelling; however, urinary bladder herniation into this defect may cause severe, potentially fatal postrenal uremia with depression and vomiting.

# Diagnosis

Digital rectal examination should detect rectal deviation, lack of muscular support, and/or a rectal diverticulum. The clinician should check for retroflexion of the urinary bladder into the hernia. If such herniation is suspected, it can be confirmed by ultrasonography, radiographs, catheterizing the bladder, or aspirating the swelling (after imaging) to see if urine is present.

#### Treatment

Animals with postrenal uremia constitute an emergency; the bladder should be emptied and repositioned, and intravenous fluids should be administered. The preferred treatment is surgical reconstruction of the muscular support; however, surgery may fail, and clients should be prepared for the fact that their pet may require additional reconstructive procedures.

# **Prognosis**

The prognosis is fair to guarded.

#### PERIANAL FISTULAE

#### Etiology

The cause of perianal fistulae is unknown. Impacted anal crypts and/or anal sacs have been hypothesized to become infected and rupture into deep tissues. An immune-mediated mechanism is likely to be involved, as seen by the clinical response to immunosuppressive drugs.

#### **Clinical Features**

Perianal fistulae occur in dogs and are more common in breeds with a sloping conformation and/or a broad base to the tail head (e.g., German Shepherd Dogs). There are typically one or more painful draining tracts around the anus. Animals are usually presented because of constipation (caused by the pain), odor, rectal pain, and/or rectal discharge.

# Diagnosis

Diagnosis is made by physical and rectal examination. Care should be taken when examining the patient because the rectal area can be very painful. Draining tracts are sometimes absent, but granulomas and abscesses can be palpated via the rectum. Rectal pythiosis rarely mimics perianal fistulae.

#### **Treatment**

Most affected dogs are cured with immunosuppressive therapy (e.g., cyclosporine, 3 to 5 mg/ kg q12h or azathio-

prine, 50 mg/m² q48h, or topical 0.1% tacrolimus q24h to q12h) with or without antibacterial drugs (e.g., metronidazole, erythromycin). Administering oral ketoconazole (5 mg/kg q12h) may allow a lower dose of cyclosporine to be effective, thus decreasing the client's cost. If cyclosporine is used, the clinician should monitor therapeutic blood levels of the drug to ensure that adequate blood levels are present. Hypoallergenic diets may also be beneficial. Rarely, animals will not respond to medical therapy and will require surgery. Surgery may cause fecal incontinence. Postoperative care is important and consists of keeping the area clean. Fecal softeners are sometimes useful.

# **Prognosis**

Many patients are treated successfully. However, the prognosis is guarded, and repeated medical care or surgeries may be needed.

# **ANAL SACCULITIS**

# Etiology

In anal sacculitis the anal sac becomes infected, resulting in an abscess or cellulitis.

#### **Clinical Features**

Anal sacculitis is relatively common in dogs and occasionally occurs in cats. Small dogs (e.g., Poodles, Chihuahuas) probably have a higher incidence of this disorder than other breeds. Mild cases cause irritation (i.e., scooting, licking, or biting the area). Anal sacs occasionally bleed onto the feces. Severe cases may be associated with obvious pain, swelling, and/or draining tracts. Dyschezia or constipation may develop because the animal refuses to defecate. Fever may occur in dogs and cats with severe anal sacculitis.

# Diagnosis

Physical and rectal examination is usually diagnostic. The anal sacs are often painful; the sac contents may appear purulent, bloody, or normal but increased in volume. In severe cases it may be impossible to express the affected sac. If the sac ruptures, the fistulous tract is usually in a 4 o'clock or 7 o'clock position in relation to the anus. Occasionally, there is an obvious abscess.

#### **Treatment**

Mild cases require only that the anal sac be expressed and an aqueous antibiotic-corticosteroid preparation be infused. Infusion with saline solution may aid in expressing impacted sacs. If clients express the anal sacs at home, they can often prevent impaction and reduce the likelihood of severe complications.

Abscesses should be lanced, drained, flushed, and treated with a hot pack; systemic antibiotics should also be administered. Hot packs also help soft spots form in early abscesses. If the problem recurs, is severe, or is nonresponsive to medical therapy, affected sacs can be resected.

# **Prognosis**

The prognosis is usually good.

# PERIANAL NEOPLASMS

# ANAL SAC (APOCRINE GLAND) ADENOCARCINOMA

# **Etiology**

Anal sac adenocarcinomas are derived from the apocrine glands and are usually found in older female dogs.

#### **Clinical Features**

An anal sac or pararectal mass can often be palpated, but some are not obvious. Paraneoplastic hypercalcemia causing anorexia, weight loss, vomiting, and polyuria-polydipsia is common. Occasionally, constipation occurs as a result of the hypercalcemia or perineal mass. Metastatic sublumbar lymphadenopathy occurs early in the course of the disease, but metastases to other organs are rare.

# Diagnosis

Cytologic and/or histopathologic evaluation is necessary to establish a diagnosis. Hypercalcemia in an older female dog should lead to careful examination of both anal sacs and pararectal structures. Abdominal ultrasonography may reveal sublumbar lymphadenopathy.

#### **Treatment**

Hypercalcemia, if present, must be treated (see Chapter 55). The tumor should be removed, but these tumors have often metastasized to regional lymph nodes by the time of diagnosis. Palliative chemotherapy (see Chapter 77) may be transiently beneficial in some dogs.

# **Prognosis**

The prognosis is guarded.

# **PERIANAL GLAND TUMORS**

#### Etiology

Perianal gland tumors arise from modified sebaceous glands. Perianal gland adenomas have testosterone receptors.

#### **Clinical Features**

Perianal gland adenomas are often sharply demarcated, raised, and red and may be pruritic. Commonly found around the anus and base of the tail, they may be solitary or multiple and can occur over the entire back half of the dog. Male hormones appear to stimulate their growth, and they are often found in older intact male dogs (especially Cocker Spaniels, Beagles, and German Shepherd Dogs). Pruritus may lead to licking and ulceration of the tumor. Perianal gland adenocarcinomas are rare; they are usually large, infiltrative, ulcerated masses with a high metastatic potential.

# Diagnosis

Cytologic and/or histopathologic evaluation is needed for diagnosis, but neither reliably distinguishes malignant from benign masses. Finding metastases (e.g., regional lymph nodes, lungs) is the most certain method of diagnosing malignancy.

#### **Treatment**

Surgical excision is preferred for benign or solitary tumors that have not metastasized. Neutering is recommended for dogs with adenomas. Radiation is recommended for multicentric and some malignant tumors. Chemotherapy (vincristine, adriamycin, cyclophosphamide [VAC] protocol) is helpful in dogs with adenocarcinomas (see Chapter 77).

# **Prognosis**

The prognosis is good for benign lesions but guarded for malignant lesions.

# CONSTIPATION

Constipation may be caused by any perineal or perianal disease that causes pain (e.g., perianal fistulae, perineal hernia, anal sacculitis), obstruction, or colonic weakness. It may also be caused by other disorders (see Box 28-15).

# PELVIC CANAL OBSTRUCTION CAUSED BY MALALIGNED HEALING OF OLD PELVIC FRACTURES

# Etiology

Prior trauma (e.g., automobile-associated injuries) is a common cause of pelvic canal obstruction in cats because they frequently sustain pelvic trauma that heals if they are allowed to rest. Cats appear clinically normal once the fractures heal, but the diminution of the pelvic canal can produce megacolon and/or dystocia.

## Diagnosis

Digital rectal examination should be diagnostic. Radiographs will further define the extent of the problem.

# **Treatment**

Constipation caused by minimal pelvic narrowing may be controlled with stool softeners, but orthopedic surgery may be needed. The prognosis depends somewhat on how severely the colon has been distended. Unless the colon is massively stretched out of shape, it can often resume function if it is kept empty and allowed to regain its normal diameter. Prokinetic drugs such as cisapride (0.25 mg/kg administered orally q8-12h) may stimulate peristalsis; however, prokinetic drugs must not be used if there is residual obstruction.

#### **Prognosis**

The prognosis depends on the severity and chronicity of colonic distention and the success of surgery in widening the pelvic canal.

# BENIGN RECTAL STRICTURE

# Etiology

The cause is uncertain but may be congenital.

#### Clinical Features

Constipation and tenesmus are the principal clinical signs.

# Diagnosis

Digital rectal examination detects a stricture, although this sign can be missed if a large dog is palpated carelessly or if the stricture is beyond reach. Proctoscopy and evaluation of a deep biopsy specimen (i.e., including submucosa) of the stricture are needed to confirm that the lesion is benign and fibrous as opposed to neoplastic or fungal.

#### **Treatment**

In some animals, simple dilation via balloon or retractor will tear the stricture and allow normal defecation; other animals require surgery. Owners should be warned that strictures may re-form during healing, and surgery can cause incontinence in rare cases. Corticosteroids (prednisolone, 1.1 mg/ kg/day) might impede stricture re-formation.

# Prognosis

The prognosis is guarded to good.

# DIETARY INDISCRETION LEADING TO CONSTIPATION

Etiology Dogs often eat inappropriate foods or other materials (e.g., paper, popcorn, hair, bones). Excessive dietary fiber supplements can cause constipation if the animal becomes dehydrated.

# Diagnosis

Dietary causes are common in dogs that eat trash. Dietary indiscretion is best diagnosed by examining fecal matter retrieved from the colon.

## Treatment

Controlling the pet's eating habits, adding appropriate amounts of fiber to the diet, and feeding a moist diet (especially in cats) help prevent constipation. Repeated retention and cleansing (not hypertonic) enemas may be needed. Manual disruption of hard feces should be avoided, but if it is necessary, the animal should be anesthetized to help prevent colonic trauma during the procedure, and sponge forceps or curved hemostats should be used to mechanically break apart the feces. It often helps to insert a rigid colonoscope up to the fecal mass and then insert a tube with a vigorous stream of running water at body temperature issuing from the tip. This will soften the fecal mass and wash away debris that breaks off.

# **Prognosis**

The prognosis is usually good. The colon should function normally after cleansing unless the distention has been prolonged and severe.

# IDIOPATHIC MEGACOLON

The cause is unknown but may involve behavior (i.e., refusal to defecate) or altered colonic neurotransmitters.

# Clinical Features

Idiopathic megacolon is principally a feline disease, although dogs are occasionally affected. Affected animals may be depressed and anorectic and are often presented because of infrequent defecation.

# Diagnosis

Diagnosis requires palpating a massively dilated colon (not one just filled to normal capacity) plus elimination of dietary, behavioral, metabolic, and anatomic causes. Abdominal radiographs should be evaluated if proper abdominal palpation cannot be performed.

#### Treatment

Impacted feces must be removed. Multiple warm water retention and cleansing enemas over 2 to 4 days usually work. Future fecal impaction is prevented by adding fiber to a moist diet (e.g., Metamucil, pumpkin pie filling), making sure clean litter is always available, and using osmotic laxatives (e.g., lactulose) and/or prokinetic drugs (e.g., cisapride). Lubricants are not helpful, because they do not change fecal consistency. If this conservative therapy fails or is refused by the client, subtotal colectomy is indicated in cats (not dogs). Cats typically have soft stools for a few weeks postoperatively, some for the rest of their lives.

#### **Prognosis**

The prognosis is fair to guarded. Many cats respond well to conservative therapy if treated early.

INFLAMMATORY DISEASES

Septic Peritonitis
Sclerosing, Encapsulating Peritonitis
HEMOABDOMEN

Abdominal Hemangiosarcoma
MISCELLANEOUS PERITONEAL DISORDERS

Abdominal Carcinomatosis Mesothelioma Feline Infectious Peritonitis

# **INFLAMMATORY DISEASES**

# SEPTIC PERITONITIS

#### Etiology

Spontaneous septic peritonitis is usually caused by alimentary tract perforation or devitalization caused by neoplasia, ulceration, intussusception, foreign objects, or dehiscence of suture lines. Septic peritonitis can also develop after abdominal gunshot wounds, surgery, or hematogenous spread from elsewhere. Cats seemingly can develop spontaneous septic peritonitis.

#### **Clinical Features**

If septic peritonitis occurs secondary to suture line dehiscence, it classically manifests 3 to 6 days postoperatively. Dogs with two or more of the following have been reported to be at increased risk for dehiscence: serum albumin <2.5 g/dl, intestinal foreign body, and preoperative peritonitis. Dogs with septic peritonitis are usually depressed, febrile, and vomiting and may have abdominal pain (if they are not too depressed to respond). Abdominal effusion is usually mild to modest in amount. Signs usually progress rapidly until septic shock (i.e., systemic inflammatory response syn-

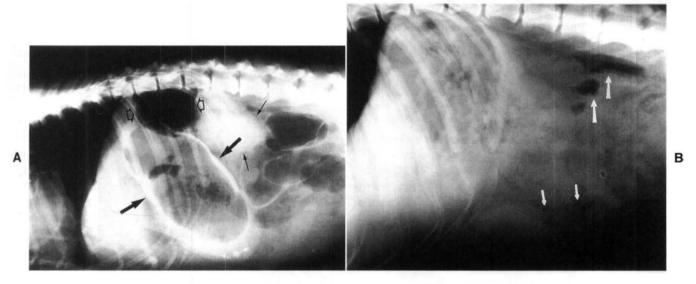

drome [SIRS]) occurs. However, some animals with septic peritonitis may have mild vomiting, slight fever, and copious volumes of abdominal fluid and feel relatively well for days or longer. In particular, cats with septic peritonitis may not show signs of abdominal pain and may be bradycardic.

# Diagnosis

Most animals with septic peritonitis have small amounts of abdominal fluid that cannot be detected by physical examination but that decrease serosal detail on plain abdominal radiographs (much like what is seen in animals with a lack of body fat). Ultrasonography is a sensitive means for detecting such small fluid volumes. Free peritoneal gas not related to recent abdominal surgery strongly suggests alimentary tract leakage (Fig. 34-1) or infection with gas-forming bacteria. Ultrasonography may detect masses (e.g., tumors) responsible for such leakage. Neutrophilia is common but nonspecific in dogs and cats with septic peritonitis.

Abdominocentesis is indicated if free abdominal fluid is detected or if septic peritonitis is suspected. Retrieved fluid is examined cytologically and cultured. Ultrasound guidance should allow the clinician to sample effusions, even when only minimal amounts are present.

Bacteria (especially if phagocytized by white blood cells) or fecal contents in abdominal fluid are diagnostic for septic peritonitis (Fig. 34-2). However, fecal contents and bacteria are often not seen despite severe infection. Prior antibiotic use may greatly suppress bacterial numbers and the percentage of neutrophils demonstrating degenerative changes. Furthermore, mild degenerative changes are common after recent abdominal surgery. More important, it is almost impossible to quickly distinguish septic peritonitis from sterile pancreatitis in some dogs without exploratory laparotomy. Both can cause SIRS, and ultrasound is not as sensitive in detecting pancreatitis as desired. Effusion lactate levels are not accurate in distinguishing septic from nonseptic effusions. Degenerative neutrophils are suggestive of septic peritonitis, but severe sterile pancreatitis can produce degenerative changes identical to that seen with infection. Unfor-

A, Plain lateral abdominal radiograph of a dog. Visceral margins of kidney (small solid arrows) and stomach (large solid arrows) are outlined by negative contrast (i.e., air). In addition, there are pockets of free air in the abdomen (open arrows). This dog had a gastric ulcer that spontaneously perforated. B, Plain lateral radiograph of a dog with a splenic abscess. There are air bubbles in the region of the spleen (short arrows) and free gas in the dorsal peritoneal cavity (long arrows).

tunately, when septic peritonitis is strongly suspected, the clinician typically cannot wait for results of abdominal fluid culture. At this time, the ability of canine pancreatic lipase-immunoreactivity determinations to discriminate between the two is uncertain, especially since dogs with septic peritonitis may have secondary pancreatitis if the intestinal perforation is close to the pancreas. Therefore the clinician should always warn the client that the patient may or may not need the procedure but that there is no quick, reliable way to distinguish before surgery.

# **Treatment**

Animals with spontaneous septic peritonitis usually have an alimentary tract leak and should be surgically explored as soon as they are stable. A preanesthetic complete blood count (CBC), serum biochemistry profile, and urinalysis are desirable; however, surgery usually should not be delayed even if the laboratory results are. During surgery a careful search should be made for intestinal or gastric defects. Biopsy of tissue surrounding a perforation should be performed to search for underlying neoplasia or inflammatory bowel disease (IBD). After the defect is corrected, the abdomen should be repeatedly lavaged with large volumes of warm crystalloid solutions to dilute and remove debris and bacteria. The abdomen cannot be adequately lavaged via a drain tube or even a peritoneal dialysis catheter except in the mildest cases. Adhesions re-form quickly; they should not be broken down unless it is necessary to examine the intestines. Intestines should be resected only if they are truly devitalized. Intestines are sometimes unnecessarily removed because of adhesions, resulting in short bowel syndrome (see p. 466), which has substantial morbidity.

Substantial abdominal contamination may require protracted drainage. Penrose drains are typically inadequate for this purpose. Open abdominal drainage may be done, but it is very time and labor intensive. A nonabsorbable suture is used to close the abdomen except for a 6- to 8-cm opening at its most dependent aspect. This open incision is covered with sterile absorbent dressings (e.g., a sterile sanitary napkin held in place by sterile cast padding and sterile gauze) that are changed as needed, usually two to four times per day initially. Eventually, only one change per day will be needed. When the dressing is changed, a sterile, gloved hand should explore the opening to ensure that omentum and intestines have not blocked the site. This dressing change regimen is continued until abdominal drainage decreases and most or all of the peritoneal contamination is gone. Then a second surgery is performed to close the abdomen. The opening sometimes closes spontaneously. The abdomen should be recultured at the time of the second surgery. Alternatively, closed suction drains have been used postoperatively with success, and some clinicians advocate closure of such abdomens without drainage.

Systemic antimicrobial therapy should consist of broad-spectrum, parenteral antibiotics. A combination of a plactam drug (e.g., ticarcillin plus clavulinic acid) and metronidazole plus an aminoglycoside (e.g., amikacin) is usually an excellent choice (see the discussion of antibacterial drugs used in gastrointestinal disorders, p. 409). Enrofloxacin may be substituted for the aminoglycoside, but it must be

**FIG 34-2 A,** Photomicrograph of peritoneal exudate from a dog with septic peritonitis. Note bacteria (small arrows) and neutrophils that have degenerated so much that it is difficult to identify them as neutrophils (large arrows). (Wright's stain; magnification ×1000.) (Courtesy Dr. Claudia Barton, Texas A & M University.) **B,** Photomicrograph of septic peritoneal fluid. There is one intracellular bacterium (large arrow) and two things (small, clear arrows) that may or may not be bacteria. The neutrophils are not nearly as degenerated as in **A**.

given over 30 to 40 minutes in a diluted form. Aminoglycosides and quinolones are dose-dependent drugs; administration of the entire daily dose in one injection is safer and probably as or more effective than administering smaller doses two to three times daily. Cefoxitin (30 mg/kg q6-8h) and meropenem (24 mg/kg once daily) are other  $\beta$ -lactam drugs that may be used. Fluid and electrolyte support helps prevent aminoglycoside-induced nephrotoxicity. Hypoalbuminemia can occur, especially if open abdominal drainage is used. If disseminated intravascular coagulation (DIC) is present, administration of fresh frozen plasma to replenish antithrombin III (AT III) and other clotting

factors is optimal; plasma is given until the AT III concentration and the prothrombine time (PT) and partial thromboplastin time (PTT) are normal or clearly much improved. Heparin may also be administered; low molecular weight heparin is believed to be more effective than unfractionated heparin.

#### **Prognosis**

The prognosis depends on the cause of the leak (e.g., perforations may be caused by malignancies) and the animal's condition when it is diagnosed. SIRS and DIC worsen the prognosis.

## SCLEROSING, ENCAPSULATING PERITONITIS

#### Etiology

Reported causes include bacterial infection, steatitis, and fiberglass ingestion. This form of peritonitis is rare.

#### **Clinical features**

Sclerosing, encapsulating peritonitis is a chronic condition in which abdominal organs are covered and encased in heavy layers of connective tissue. Typical clinical signs usually include vomiting, abdominal pain, and ascites. During exploratory surgery the lesions may mimic those of a mesothelioma. Analysis of abdominal fluid usually reveals red blood cells, mixed inflammatory cells, and macrophages. Diagnosis is confirmed by surgical biopsy of the thick covering of the abdominal organs.

#### Treatment

Antibiotics with or without corticosteroids may be tried. Removal of underlying causes (e.g., steatitis in cats) is desirable, but such causes are rarely found.

#### **Prognosis**

Most affected animals die despite therapeutic attempts.

#### **HEMOABDOMEN**

Most red effusions are blood-tinged transudates, not hemoabdomen. Hemoabdomen is usually indicated by a fluid with a hematocrit greater than or equal to 10% to 15%. Blood in the abdominal cavity can be iatrogenic (i.e., caused by abdominocentesis), traumatic (e.g., automobile-associated trauma), or toxic (e.g., ingestion of vitamin K antagonist) in origin, or can represent spontaneous disease. Clots or platelets in the sample mean that the bleeding is iatrogenic or is currently occurring near the site of the abdominocentesis. Spontaneous hemoabdomen is usually the result of a bleeding neoplasm (e.g., hemangiosarcoma, hepatocellular carcinoma). History, physical examination, coagulation studies, and/or abdominal ultrasonography usually establish the diagnosis. It should be noted that thrombocytopenia may cause or be caused by vigorous abdominal bleeding. Also, even when a coagulopathy is secondary to the original cause of the hemoabdomen (e.g., tumor), it may become severe enough to cause bleeding by itself.

#### ABDOMINAL HEMANGIOSARCOMA

#### Etiology

Abdominal hemangiosarcoma often originates in the spleen (see Chapter 82). It can spread throughout the abdomen by implantation, causing widespread peritoneal seepage of blood, or it can metastasize to distant sites (e.g., liver, lungs).

#### Clinical features

Abdominal hemangiosarcoma is principally found in older dogs, especially German Shepherd Dogs and Golden Retrievers. Anemia, abdominal effusion, and periodic weakness or collapse from poor peripheral perfusion are common presenting complaints. Some animals have bicavity hemorrhagic effusion.

#### Diagnosis

Ultrasonography is the most sensitive test for splenic and hepatic masses, especially when there is copious abdominal effusion. Radiographs may reveal a mass if there is minimal free peritoneal fluid. Abdominocentesis typically reveals hemoabdomen but not neoplastic cells. Definitive diagnosis requires biopsy (via laparotomy) because splenic hematoma, hemangioma, and widespread accessory splenic tissue masquerade as hemangiosarcoma but have a much better prognosis. Two or more large tissue samples should always be submitted, and the clinician should be prepared to request recuts; hemangiosarcoma may be difficult to find histologically. Fine-needle biopsy (especially fine-needle core biopsy) is sometimes diagnostic. However, there is the risk of inducing life-threatening hemorrhage, and the patient must be watched closely after the procedure for evidence of hypovolemia.

#### **Treatment**

Solitary masses should be excised. Chemotherapy may be palliative for some animals with multiple masses; chemotherapy is also indicated as an adjuvant postoperative treatment modality (see Chapter 82).

#### **Prognosis**

The prognosis is poor because the tumor metastasizes early.

## MISCELLANEOUS PERITONEAL DISORDERS

#### **ABDOMINAL CARCINOMATOSIS**

#### Etiology

Abdominal carcinomatosis involves widespread, miliary peritoneal carcinomas that may have originated from various sites; intestinal and pancreatic adenocarcinomas are common neoplasms that may result in carcinomatosis.

#### **Clinical Features**

Weight loss may be the predominant complaint, although some animals are presented because of obvious abdominal effusion.

#### Diagnosis

Physical examination and radiography rarely help to establish the diagnosis. Ultrasonography may reveal masses or infiltrates if they are large enough; however, small, miliary lesions can be missed by ultrasound. Fluid analysis reveals a nonseptic exudate or a modified transudate; epithelial neo-

plastic cells are occasionally found (see Chapter 36). Laparoscopy or abdominal exploratory surgery with histologic examination of biopsy specimens is usually needed for diagnosis.

#### **Treatment**

Intracavitary chemotherapy has been palliative for some animals, although generally there is no effective treatment for this disorder. Cisplatin (50 to 70 mg/m² every 3 weeks) and 5-fluorouracil (150 mg/m² every 2 to 3 weeks) are frequently effective in decreasing fluid accumulation in dogs with carcinomatosis but should not be used in cats; carboplatin (150 to 200 mg/m² every 3 weeks) may be effective in cats.

#### **Prognosis**

The prognosis is grim.

#### MESOTHELIOMA

#### Etiology

The cause is unknown.

#### **Clinical Features**

Mesothelioma often causes bicavity effusion. The tumor may appear as fragile clots adhering to the peritoneal surface of various organs.

#### Diagnosis

Imaging reveals only fluid accumulations. Fluid cytology rarely is beneficial because reactive mesothelial cells are notorious for mimicing malignancy, and pathologists generally acknowledge the inability to cytologically distinguish neoplastic cells from nonneoplastic cells in abdominal fluid. Laparoscopy or laparotomy are typically needed to make a definitive diagnosis.

#### **Treatment**

Intracavity cis-platinum may be attempted.

#### **Prognosis**

The prognosis is grim, but chemotherapy has been reported to prolong survival by several months.

#### **FELINE INFECTIOUS PERITONITIS**

Feline infectious peritonitis (FIP) is a viral disease of cats, which is discussed in detail in Chapter 97. Only the abdom-

inal effusion of FIP is discussed here. Although a major cause of feline abdominal effusion, FIP is not the only cause. Furthermore, not all cats with FIP have effusions. FIP effusions are classically pyogranulomatous (i.e., macrophages and nondegenerate neutrophils) with a relatively low nucleated cell count (i.e.,  $\leq 10,000/\mu$ l). However, some cats with FIP have effusions that primarily contain neutrophils. A nonseptic exudate in a nonazotemic cat suggests FIP until proven otherwise.

Xylazine	Rompun	1.1 mg/kg IV; 2.2 mg/kg SC, IM	(cats) 0.4-0.5 mg/kg IM or IV for emesis	

## PART FOUR

# HEPATOBILIARY AND EXOCRINE PANCREATIC DISORDERS

Penny J. Watson and Susan E. Bunch

CHAPTER

## Clinical Manifestations of Hepatobiliary Disease

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS ABDOMINAL ENLARGEMENT

Organomegaly
Abdominal Effusion
Abdominal Muscular Hypotonia
JAUNDICE, BILIRUBINURIA, AND CHANGE IN FECAL
COLOR
HEPATIC ENCEPHALOPATHY
COAGULOPATHIES
POLYURIA AND POLYDIPSIA

#### **GENERAL CONSIDERATIONS**

Clinical signs of hepatobiliary disease in cats and dogs can be extremely variable, ranging from anorexia and weight loss to abdominal effusion, jaundice, and hepatic coma (Box 35-1). However, none of these signs are pathognomonic for hepatobiliary disease, and they must be distinguished from identical signs caused by disease of other organ systems. The severity of the clinical sign does not necessarily correlate with the prognosis or with the degree of liver injury, although several of these signs are often seen together in dogs and cats with end-stage hepatic disease (e.g., ascites, metabolic encephalopathy from hepatocellular dysfunction, and acquired portosystemic venous shunting with gastrointestinal bleeding); however, ascites has recently been shown to be a significant negative prognostic indicator in dogs with chronic hepatitis. At the opposite end of the spectrum of hepatobiliary disease, because of the tremendous reserve capacity of the liver, there may be no clues for the presence of a hepatic disorder except for abnormal screening blood test results obtained before an elective anesthetic procedure.

#### ABDOMINAL ENLARGEMENT

#### **ORGANOMEGALY**

Abdominal enlargement may be the presenting complaint of owners of cats and dogs with hepatobiliary disease, or it may be noted during physical examination. Organomegaly, fluid expansion of the peritoneal space, or poor abdominal muscle tone is usually the cause of this abnormality.

Enlarged organs that most often account for increased abdominal size are the liver, the spleen (see Chapter 88), and occasionally the kidneys (see Chapter 41). Normally, the liver is palpable just caudal to the costal arch along the ventral body wall in the cat and dog, but it may not be palpable at all. Inability to palpate the liver, especially in dogs, does not automatically mean that the liver is abnormally small. In lean cats it is usually possible to palpate the diaphragmatic surface of the liver. In cats or dogs with pleural effusion or other diseases that expand thoracic volume, the liver may be displaced caudally and erroneously appear to be enlarged.

Liver enlargement is much more common in cats than in dogs with liver disease. Dogs more often have reduced liver size because of chronic hepatitis with fibrosis. The pattern of liver enlargement may be generalized or focal, depending on the cause. Infiltrative and congestive disease processes or those that stimulate hepatocellular hypertrophy or mononuclear-phagocytic system (MPS) hyperplasia tend to result in smooth or slightly irregular, firm, diffuse hepatomegaly. Focal or asymmetrical hepatic enlargement is often seen with proliferative or expansive diseases that form solid or cystic mass lesions. Examples of such diseases are listed in Table 35-1.

Smooth, generalized hepatosplenomegaly may be associated with nonhepatic causes, such as increased intravascular hydrostatic pressure (passive congestion) secondary to right-sided congestive heart failure or pericardial disease. In rare instances hepatic vein occlusion (Budd-Chiari syndrome)

BOX 35-1

Clinical Signs and Physical Examination Findings in Cats and Dogs with Hepatobiliary Disease

General, Nonspecific
Anorexia
Depression
Lethargy
Weight loss
Small body stature
Poor or unkempt haircoat
Nausea, vomiting
Diarrhea
Dehydration
Polydipsia, polyuria
More Specific But Not Pathognomonic
Abdominal enlargement (organomegaly, effusion, or mus- cular hypotonia) Jaundice, bilirubinuria, acholic feces Metabolic encephalopathy Coagulopathies

results in similar findings. Hepatosplenomegaly in icteric dogs or cats may be attributable to benign MPS hyperplasia and extramedullary hematopoiesis secondary to immunemediated hemolytic anemia or to infiltrative processes such as lymphoma, systemic mast cell disease, or myeloid leukemia.

Another cause of hepatosplenomegaly is primary hepatic parenchymal disease with sustained intrahepatic portal hypertension. In dogs and cats with this syndrome, the liver is usually firm and irregular on palpation and often the liver itself is reduced in size as a result of fibrosis; however, the spleen can be enlarged and congested as a result of portal hypertension. For conditions that involve primarily the spleen, see Chapter 88.

#### ABDOMINAL EFFUSION

Abdominal effusion is much more common in dogs than in cats with liver disease. With the exception of liver disease associated with feline infectious peritonitis (FIP), cats with liver disease rarely have ascites. The pathogenesis of abdominal effusion in cats and dogs with hepatobiliary disease is determined by chemical and cytologic analysis of a fluid specimen (Fig. 35-1; see also Table 36.1). On the basis of cell and protein content, abdominal fluids are classified by standard criteria as transudates, modified transudates (moderate to low cellularity with moderate to low protein concentration), or chyle or blood (see Table 36-1). The term *ascites* is reserved for fluid of low to moderate protein content and low to moderate cell count (transudate or modified transudate) and is usually related to disorders of hepatic or cardiovascu-

Differential Diagnoses for Changes in Hepatic Size

lar origin or severe protein-losing enteropathy or nephropathy. A small amount of effusion is suspected when abdominal palpation yields a "slippery" sensation during physical examination. Moderate-to-large-volume effusion is frequently conspicuous but may distend the abdomen so

<sup>†</sup>Loss of portal blood flow to one lobe can cause the lobe to atrophy. *C,* Primarily cats; *D,* primarily dogs; *C, D,* cats and dogs.

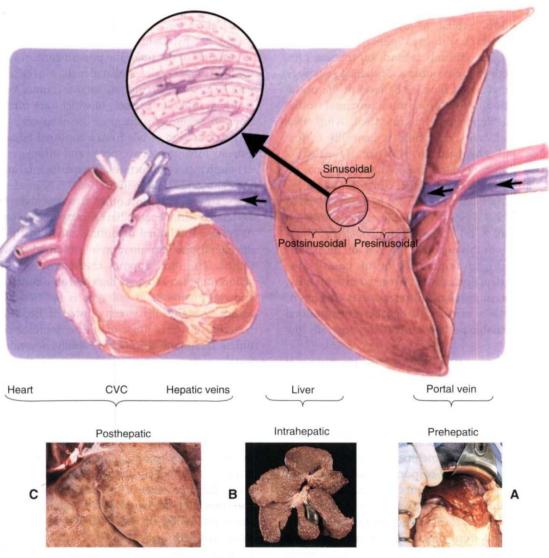

FIG 35-1

Mechanisms of abdominal fluid accumulation associated with altered portal and hepatic blood flow and clinical correlates. PREHEPATIC: arteriovenous fistula (A) or portal vein obstruction or hypoplasia; INTRAHEPATIC presinusoidal: periportal fibrosis or portal venule hypoplasia; INTRAHEPATIC sinusoidal: cellular infiltrates or collagen (B); INTRAHEPATIC postsinusoidal: central (terminal hepatic) venular fibrosis; POSTHEPATIC (passive congestion): obstruction of hepatic veins or intrathoracic caudal vena cava, right-sided heart failure (C) or pericardial disease. Arrow indicates direction of venous blood flow. (From Johnson SE: Portal hypertension. I. Pathophysiology and clinical consequences, Compend Contin Educ 9:741, 1987.)

much that details of abdominal organs are obscured during palpation. Whether there is small- or large-volume effusion, the general pathogeneses of third-space fluid accumulation (excessive formation by increased venous hydrostatic pressure, decreased intravascular oncotic pressure, or altered vascular permeability and insufficient resorption), singly or in combination, apply to cats and dogs with hepatobiliary diseases. In addition, an important part of the mechanisms of ascites formation in dogs with liver disease is activation of the renin-angiotensin-aldosterone system (RAAS) with

sodium retention by the kidneys and increased circulating fluid volume. This RAAS activation is triggered by a decrease in systemic blood pressure caused by pooling of a significant proportion of the circulating blood volume in the splanchnic circulation. It has been observed that, in many cases, overt ascites does not develop until sodium retention by the kidneys is increased, altering the balance of fluid formation and reabsorption. Therefore aldosterone antagonists play a key role in the treatment of ascites associated with liver disease.

Intrahepatic portal venous hypertension is the most common mechanism leading to ascites in companion animals, particularly dogs, with hepatobiliary diseases. The formation of abdominal effusion depends on the site, rate, and degree of defective venous outflow. Sustained resistance to intrahepatic portal blood flow at the level of the portal triad favors exudation of fluid from more proximal (in the direction of portal blood flow; i.e., intestinal) lymphatics into the abdominal cavity. The fluid is generally of low protein content and is hypocellular. However, if the fluid is present in the abdomen for any amount of time, it becomes "modified" with an increase in protein content. The exception to this is in the animal with marked hypoalbuminemia associated with liver disease in which the ascites remains a low-protein transudate. Inflammatory or neoplastic cellular infiltrates or fibrosis in this region of the liver are the pathologic processes most often responsible for this type of effusion. Sinusoidal obstruction caused by regenerative nodules, collagen deposition, or cellular infiltrates causes effusion of a fluid composed of a mixture of hepatic and intestinal lymph that has a variable protein content and generally low cell count.

Prehepatic portal venous occlusion or the presence of a large arteriovenous fistula, leading to portal venous volume overload, and associated high intrahepatic vascular resistance triggered by increased portal flow also produces a low to moderate protein, hypocellular effusion, as would diffuse mesenteric lymphatic obstruction associated with lymphoma. The latter can also sometimes result in a chylous effusions. Examples of causes of portal venous occlusion include intrahuminal obstructive masses (e.g., thrombus), extrahuminal compressive masses (e.g., mesenteric lymph node, neoplasm), and portal vein hypoplasia or atresia.

Venous congestion from disease of the major hepatic veins and/or distally (i.e., thoracic caudal vena cava, heart; posthepatic venous congestion) increases formation of hepatic lymph, which exudes from superficial hepatic lymphatics. Because the endothelial cell-lined sinusoids are highly permeable, hepatic lymph is of high protein content. Abdominal effusion formed under these conditions is more likely to develop in dogs than in cats. Reactive hepatic veins that behave as postsinusoidal sphincters have been identified in dogs and are speculated to add to venous outflow impingement. Concurrent hypoalbuminemia (≤1.5 g/dl) in dogs (and rarely cats) associated with hepatic parenchymal failure may further enhance movement of fluid into the peritoneal space. Perivenular pyogranulomatous infiltrates in the visceral and parietal peritoneum of cats with the effusive form of FIP increase vascular permeability and promote exudation of straw-colored, protein-rich fluid into the peritoneal space. Typically, the fluid is of low to moderate cellularity, with a mixed cell population of neutrophils and macrophages, and with a moderate to high protein concentration. It is usually classified as an exudate but occasionally is a modified transudate.

Hepatobiliary malignancies or other intraabdominal carcinomas that have disseminated to the peritoneum can elicit an inflammatory reaction, with subsequent exudation of lymph and fibrin. The fluid may be serosanguineous, hemorrhagic, or chylous in appearance. Regardless of the gross appearance of the fluid, the protein content is variable, and the fluid may contain exfoliated malignant cells if the primary neoplasm is a carcinoma, mesothelioma, or lymphoma, although often it does not, in which case further investigations are required to diagnose the neoplasm.

Extravasation of bile from a ruptured biliary tract elicits a strong inflammatory response and stimulates transudation of lymph by serosal surfaces. In experimental animal models, the damaging component of bile has been identified as bile acids. Unlike with most other causes of abdominal effusion associated with hepatobiliary disease, there may be evidence of cranial abdominal or diffuse abdominal pain identified during physical examination in cats and dogs with bile peritonitis. The fluid appears characteristically dark orange, yellow, or green and has a high bilirubin content on analysis, and the predominant cell type is the healthy neutrophil, except when the biliary tract is infected. Because normal bile is sterile, the initial phase of bile peritonitis is nonseptic, but unless treatment is initiated rapidly, secondary infection, usually with anaerobes, may become life-threatening.

#### **ABDOMINAL MUSCULAR HYPOTONIA**

The presence of a distended abdomen in the absence of organomegaly or abdominal effusion suggests abdominal muscular hypotonia. Either the catabolic effects of severe malnutrition or (more commonly in dogs) excess endogenous or exogenous corticosteroids reduce muscular strength, giving the appearance of an enlarged abdomen. In both dogs and (much less commonly) cats with hyperadrenocorticism, the combination of generalized hepatomegaly (mild and associated with diabetes mellitus in cats), redistribution of fat stores to the abdomen, and muscular weakness causes abdominal distention.

On the basis of the physical examination findings, the problem of abdominal enlargement should be refined to the level of organomegaly, abdominal effusion, or poor muscular tone, as shown in Fig. 35-2. Additional tests are required to obtain a definitive diagnosis.

## JAUNDICE, BILIRUBINURIA, AND CHANGE IN FECAL COLOR

By definition, jaundice in cats and dogs is the yellow staining of serum or tissues by an excessive amount of bile pigment or bilirubin (Fig. 35-3); the terms *jaundice* and *icterus* may be used interchangeably. Because the normal liver has the ability to take up and excrete a large amount of bilirubin, there must be either a large, persistent increase in the production of bile pigment (hyperbilirubinemia) or a major impairment in bile excretion (cholestasis with hyperbilirubinemia) before jaundice is detectable as yellow-stained tissues (serum bilirubin concentration ≥2 mg/dl) or serum (serum bilirubin concentration ≥1.5 mg/dl).

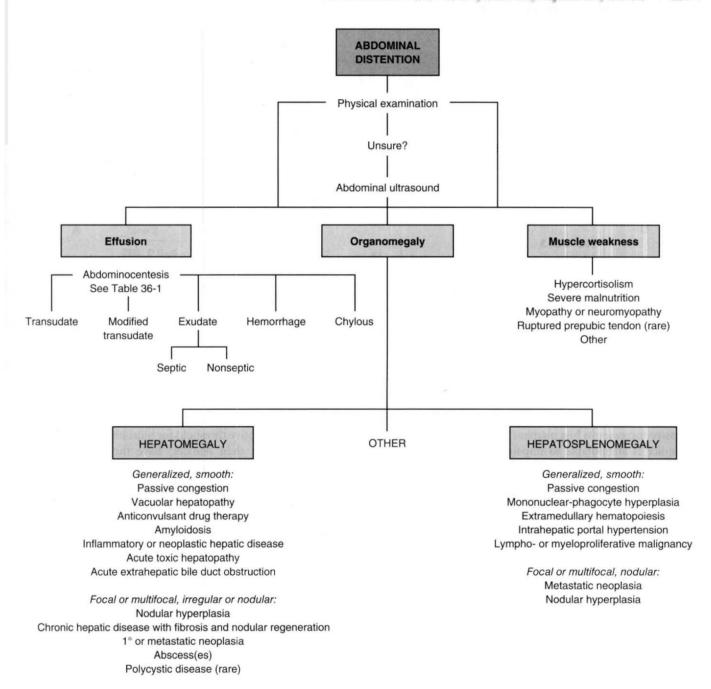

FIG 35-2

Algorithm for initial evaluation of the cat or dog with abdominal distention.

In normal animals bilirubin is a waste product of heme protein degradation. The primary source of heme proteins is senescent erythrocytes, with a small contribution by myoglobin and heme-containing enzyme systems in the liver. After phagocytosis by cells of the MPS, primarily in the bone marrow and spleen, heme oxygenase opens the protoporphyrin ring of hemoglobin, forming biliverdin. Biliverdin reductase converts biliverdin to fat-soluble bilirubin IXa, which is released into the circulation, where it is bound to albumin for transport to hepatic sinusoidal membranes. After uptake, transhepatocellular movement, and conjuga-

tion to various carbohydrates, conjugated bilirubin, now water soluble, is excreted into the bile canaliculi. Conjugated bilirubin is then incorporated into micelles and stored with other bile constituents in the gallbladder until it is discharged into the duodenum. However, in dogs it has been noted that only 29% to 53% of bile produced is stored in the gall bladder; the rest is secreted directly into the duodenum (Rothuizen et al., 1990). After arrival in the intestine, conjugated bilirubin undergoes bacterial deconjugation and then reduction to urobilinogen, with most urobilinogen being resorbed into the enterohepatic circulation. A small fraction

FIG 35-3

Jaundiced mucous membranes in a dog (A, gum, and B, sclera). Note that this dog had jaundice because of immune-mediated hemolytic anemia and not liver disease—hence the mucous membranes are pale and yellow (which makes them more easily photographed). (Photographs courtesy Sara Gould.)

of urobilinogen is then excreted in the urine, and a small portion remains in the intestinal tract to be converted to stercobilin, which imparts normal fecal color.

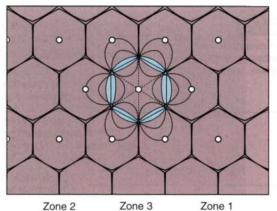

Inherited abnormalities of bilirubin metabolism have not been identified in cats and dogs; thus in the absence of massive increases in bile pigment production by hemolysis, jaundice is attributable to impaired excretion of bilirubin (and usually other constituents of bile) by diffuse intrahepatic hepatocellular or biliary disease or by interrupted delivery of bile to the duodenum. The inability to take up, intracellularly process, or excrete bilirubin into the bile canaliculi (the rate-limiting step) is the mechanism of cholestasis believed to be operational in many primary hepatocellular diseases. Jaundice is more likely to be a clinical feature if the liver disorder involves primarily the periportal (zone 1) hepatocytes (Fig. 35-4) than if the lesion involves centrilobular (zone 3) hepatocytes. Inflammation and swelling of larger intrahepatic biliary structures could similarly delay bile excretion.

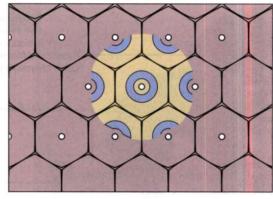

Obstruction of the bile duct near the duodenum results in increased intraluminal biliary tract pressure, interhepatocellular regurgitation of bile constituents into the circulation, and jaundice. If only one of the hepatic bile ducts exiting the liver is blocked or if only the cystic duct exiting the gallbladder is obstructed for some reason, there may be biochemical clues for localized cholestasis, such as high serum alkaline phosphatase activity; however, the liver's overall ability to excrete is preserved, and jaundice does not ensue. Traumatic or pathologic biliary tract rupture allows leakage of bile into the peritoneal space and some absorption of bile components. Depending on the underlying cause and the time elapsed between biliary rupture and diagnosis, the degree of jaundice may be mild to moderate. If biliary rupture has occurred, the total bilirubin content of the abdominal effusion is greater than that of serum.

Reference ranges for serum total bilirubin concentrations in dogs and cats may vary from laboratory to laboratory, but most published resources agree that concentrations over 0.3 mg/dl in cats and 0.6 mg/dl in dogs are abnormal. When results of laboratory tests are assessed, species differences in the formation and renal processing of bilirubin between cats and dogs must be taken into account. Canine renal tubules have a low resorptive threshold for bilirubin. Dogs (males to a greater extent than females) have the necessary renal enzyme systems to process bilirubin to a limited extent; therefore bilirubinuria (up to 2+ to 3+ reaction by dipstick analysis) may be a normal finding in canine urine specimens of specific gravity greater than 1.025. Cats do not have this ability, and they have a ninefold higher tubular absorptive capacity for bilirubin than dogs. Bilirubinuria in cats is associated with hyperbilirubinemia and is always pathologic. Because unconjugated and most conjugated bilirubin is albumin-bound in the circulation, only the small amount of nonprotein-bound conjugated bilirubin is expected to appear in the urine in physiologic and pathologic states. In dogs with hepatobiliary disease, increasing bilirubinuria often precedes the development of hyperbilirubinemia and clinical jaundice and may be the first sign of illness detected by owners.

Several nonhepatobiliary disorders impede bilirubin excretion by poorly understood means. Jaundice with evidence of hepatocellular dysfunction but minimal histopathologic changes in the liver has been described in septic human, feline, and canine patients. Certain products released by bacteria, such as endotoxin, are known to reversibly interfere with bile flow. As yet unexplained mild hyperbilirubinemia (2.5 mg/dl) may also be detected in approximately 20% of hyperthyroid cats. Experimental investigations of thyrotoxicosis in laboratory animals have demonstrated increased production of bilirubin, which has been proposed to be associated with increased degradation of hepatic heme proteins. There is no histologic evidence of cholestasis at the light microscopic level in affected cats, and the hyperbilirubinemia resolves with return to euthyroidism. Guidelines for

В

#### FIG 35-4

**A,** Rappaport scheme of the hepatic functional lobule (acinus), organized according to biochemical considerations (1958). For example, zone 1 cells are responsible for protein synthesis, urea and cholesterol production, gluconeogenesis, bile formation, and cytogenesis; zone 2 cells also produce albumin and are actively involved in glycolysis and pigment formation; and zone 3 cells are the major site of liponeogenesis, ketogenesis, and drug metabolism. Zone 3 hepatocytes, being farther from the hepatic artery and hepatic portal veins, also have the lowest oxygen supply and are therefore most susceptible to hypoxic damage. Conversely, zone 1 hepatocytes, being closest to the hepatic portal vein, are most susceptible to damage by toxins from the gut. **B,** Outdated theory of hepatic functional lobule, as first proposed in 1833. The apparent hexagonal boundaries have little to do with functional arrangement.

initial evaluation of the icteric cat or dog are given in Fig. 35-5. Finally, lipemia is a common cause of pseudohyper-bilirubinemia in dogs as a result of interference with the laboratory test.

Acholic feces result from total absence of bile pigment in the intestine (Fig. 35-6). Only a small amount of bile pigment is needed to be changed to stercobilin and yield normal fecal color; therefore bile flow into the intestine must be completely discontinued in order to form acholic feces, and this is very rare in both dogs and cats. In addition to appearing pale from lack of stercobilin and other pigments, acholic feces are pale because of steatorrhea resulting from the lack of bile acids to facilitate fat absorption. Mechanical diseases of the extrahepatic biliary tract (e.g., unremitting complete extrahepatic bile duct obstruction [EBDO], traumatic bile duct avulsion from the duodenum) are the most common causes of acholic feces in cats and dogs. Total inability to take up, conjugate, and excrete bilirubin because of generalized hepatocellular failure is theoretically possible. However, because the functional organization of the liver is heterogeneous (see Fig. 35-4) and because primary hepatic diseases do not affect all hepatocytes uniformly, the overall ability of the liver to process bilirubin may be altered, although it is usually preserved. A condition has been reported rarely in cats with severe cholangitis in which bile flow ceases. Under these circumstances, "bile" consists of only clear, viscous biliary epithelial secretions, and this may result in the production of acholic feces. A similar finding, known as "white bile syndrome," has been associated with prolonged total biliary obstruction and is thought to be the result of resorption of bile pigments. The true frequency of white bile in cats or dogs with severe cholestasis is not known.

#### HEPATIC ENCEPHALOPATHY

Signs of abnormal mentation and neurologic dysfunction develop in dogs and cats with serious hepatobiliary disease as a result of exposure of the cerebral cortex to absorbed intestinal toxins that have not been removed by the liver. Substances that have been implicated as important in the genesis of hepatic encephalopathy (HE), singly or in combination, are ammonia, mercaptans, short-chain fatty acids, skatoles, indoles, and aromatic amino acids. Either there is marked reduction in functional hepatic mass or portal blood flow has been diverted by the development of portosystemic venous anastomoses, thus preventing detoxification of gastrointestinal (GI) toxins, or there is a combination of these two processes. Portosystemic shunting can occur via the presence of a macroscopic vascular pattern that results from a congenital vascular miscommunication or by a complex of acquired "relief valves" that open in response to sustained portal hypertension secondary to severe primary hepatobiliary disease (Fig. 35-7). Intrahepatic, microscopic portosystemic shunting or widespread hepatocellular inability to detoxify noxious enteric substances accounts for HE when an abnormal portal vascular pattern cannot be demonstrated. Rarely, if congenital portovascular anomalies and severe primary hepatobiliary disease with acquired shunting have been ruled out, congenital urea enzyme cycle deficiencies

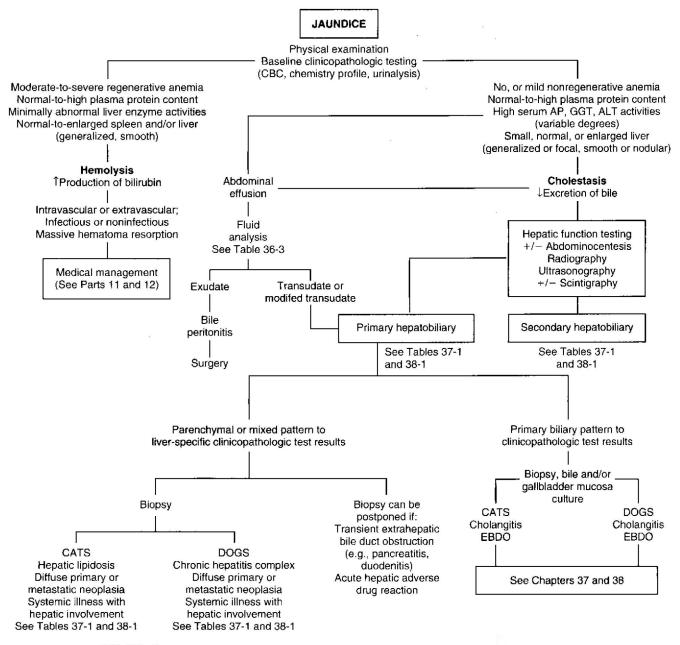

FIG 35-5
Algorithm for preliminary evaluation of the icteric cat or dog. AP, Alkaline phosphatase; GGT, γ-glutamyltransferase; ALT, alanine transaminase; EBDO, extrahepatic bile duct obstruction.

and organic acidemias, in which ammonia cannot be degraded to urea, are considered. HE has also been reported in congenital cobalamin deficiency in dogs (Battersby et al., 2005). Animals with systemic diseases having hepatic manifestations do not undergo sufficient loss of hepatic mass or change in hepatic blood flow to develop signs of HE.

The pathogenesis of this reversible abnormality in cerebral metabolism currently is incompletely understood. Increased ammonia (NH<sub>3</sub>) in the blood remains the most important cause of HE. Most of the precipitating factors and treatment recommendations for HE primarily affect blood NH3 concentrations. The effects on neurotransmitters and

the cerebrospinal fluid (CSF) environment are complex. The brain is very sensitive to the toxic effects of NH<sub>3</sub> but does not have a urea cycle, so NH<sub>3</sub> in the CSF is detoxified to glutamine. CSF glutamine concentrations in dogs with portosystemic shunts (PSS) correlate better with clinical signs than CSF or blood NH<sub>3</sub> levels (Fig. 35-8). Dogs with congenital PSS also have increased CSF concentrations of aromatic amino acids, particularly tryptophan and its metabolites, and this appears to be directly related to NH<sub>3</sub> concentrations in the CSF because they share an antiport transporter. Also implicated are changes in central nervous system (CNS) serotonin activity (which is often reduced);

FIG 35-6
Acholic feces from a 7-year-old spayed female Collie dog with a strictured bile duct and complete bile duct obstruction 3 weeks after recovery from severe pancreatitis.

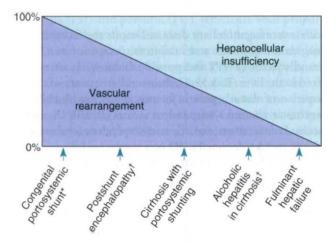

FIG 35-7
Spectrum of hepatic encephalopathy in cats and dogs ranging from pure vascular to pure hepatocellular causes.
\*, Clinically relevant only in dogs and cats; †, clinically relevant only in human patients. (Modified from Schafer DF et al: Hepatic encephalopathy. In Zakim D et al, editors: Hepatology: a textbook of liver disease, Philadelphia,

1990, WB Saunders.)

stimulation of NMDA (*N*-methyl-D-aspartic acid) receptors, peripheral-type benzodiazepine receptors, and altered astrocyte receptors and handling of glutamate. Most of these changes are related to increased NH<sub>3</sub>.

The sources of increased blood ammonia in animals with liver disease are outlined in Fig. 35-9 and include the following:

- Bacterial breakdown of undigested amino acids and purines that reach the colon
- Bacterial and intestinal urease action on urea, which freely diffuses into the colon from the blood
- Small intestinal enterocyte catabolism of glutamine as their main energy source

FIG 35-8

Two dogs with similar fasting plasma ammonia concentrations, emphasizing the lack of correlation between plasma ammonia content and severity of encephalopathic signs. **A,** Female Miniature Poodle with congenital portosystemic shunt. The plasma ammonia concentration was 454 µg/dl. **B,** Male mixed-breed dog with chronic hepatic failure and acquired portosystemic shunting. The plasma ammonia concentration was 390 µg/dl.

 Endogenous hepatic protein metabolism from excess dietary protein, GI bleeding, or breakdown of lean body mass

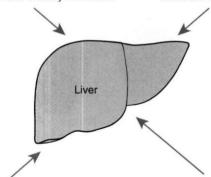

It is very important to realize that the traditional view that the toxins causing HE are predominantly of dietary origin is misleading; although the gut is an important source of NH<sub>3</sub> in animals on high-protein diets, in many animals, particularly those with protein-calorie malnutrition, endogenous sources of NH<sub>3</sub> may be more important and further dietary protein restriction just worsens the hyperammonemia in these cases.

Subtle, nonspecific signs of HE in cats and dogs that could be noted at any time and that represent chronic or subclinical HE include anorexia, depression, weight loss, lethargy, nausea, fever, hypersalivation (particularly in cats), intermittent vomiting, and diarrhea. Certain events might precipitate an acute episode of HE with severe neurologic signs (see Chapter 39). Nearly any CNS sign may be observed in cats and dogs with HE, although typical signs tend to be nonlo-

#### Ammonia derived from other organs:

Metabolism of body protein when in negative nitrogen balance Accentuated by inflammatory disease and likely by cytokines/inflammatory mediators

Hepatic transamination and deamination of amino acids for energy or to make other amino acids when excess or poor quality amino acids are fed

with severe hepatobiliary disease. Despite the fact that most coagulation proteins and inhibitors, except for von Willebrand's factor (vWF) and possibly factor VIII, are synthesized in the liver (Box 35-3), the overall frequency of clinical sequelae of disturbances in hemostasis is low. Inability to synthesize vitamin K-dependent factors (II, VII, IX, and X) because of the absence of bile acid-dependent fat absorption secondary to complete EBDO or a transected bile duct from abdominal trauma can cause clinically apparent bleeding. Subclinical and clinical coagulopathies are also noted in animals with severe diseases of the hepatic parenchyma. Some animals with severe hepatic disease and relatively unremarkable results of routine coagulation tests have high serum activity of proteins induced by vitamin K antagonism (PIVKA) that could impart bleeding tendencies. In early studies of the mechanism of impaired coagulation after partial hepatectomy in dogs, after surgical removal of 70% of the hepatic mass, dogs developed significant alterations in plasma clotting factor concentrations without spontaneous hemorrhage. Having severe hepatic parenchymal disease predisposes a dog or cat not only to changes in coagulation factor activity from hepatocellular dysfunction but also to disseminated intravascular coagulation (DIC), particularly in those with acute disease (see Chapter 38). In dogs with acute hepatic necrosis, some clinicians have observed thrombocytopenia, thought to be associated with increased platelet use or sequestration.

Other than noticeable imbalances in coagulation factor activity, the only other mechanism by which bleeding might occur in a cat or dog with severe hepatic disease is portal hypertension-induced vascular congestion and fragility. In such cases, which are expected considerably more often in dogs than in cats because of the types of hepatobiliary diseases they acquire, the common site affected is the upper GI tract (stomach, duodenum); therefore hematemesis and melena are common bleeding presentations and a common cause of death in dogs with chronic liver disease. In contrast

to human patients, in whom fragile esophageal varices develop and can burst, causing severe and often fatal hemorrhage, the mechanism of GI hemorrhage in companion animals is unknown but is suspected to be related to poor mucosal perfusion and reduced epithelial cell turnover associated with portal hypertension and splanchnic pooling of blood. Hypergastrinemia was observed in dogs made cirrhotic under experimental conditions and was theorized to have been provoked by excess serum bile acid concentrations. More recent studies have not borne out this theory; in fact, gastrin is often low in dogs with liver disease, and the ulcers are often duodenal and not gastric.

#### POLYURIA AND POLYDIPSIA

Increased thirst and volume of urination can be clinical signs of serious hepatocellular dysfunction and also of portosystemic shunts. Several factors are suspected to contribute to polydipsia (PD) and polyuria (PU), which are seen primarily in dogs and rarely in cats, with marked hepatic dysfunction. Altered sense of thirst may be a manifestation of HE. Dogs with congenital and acquired PSS have hypercortisolemia associated with reduced metabolism of cortisol in the liver and decreased cortisol binding protein concentration in the plasma. Excess secretion of adrenocorticotropic hormone stimulated by abnormal neurotransmitters leads to excess cortisol secretion and altered threshold for antidiuretic hormone release in dogs with HE. Secondary hyperaldosteronism from delayed excretion of aldosterone, which is accomplished normally by the liver, leads to sodium reten-

tion and increased water intake with compensatory PU. Changes in the function of portal vein osmoreceptors that stimulate thirst without hyperosmolality are also thought to be partly responsible for PD. Loss of the renal medullary concentrating gradient for urea because of the inability to produce urea from ammonia would first cause PU and then compensatory PD. Delayed cortisol excretion and persistent hypokalemia may also contribute to the renal concentrating defect. Investigation of polydipsia in dogs with congenital PSS has identified partial renal concentrating ability in response to water deprivation, with resolution of PD when normal portal blood flow was reestablished.

#### DIAGNOSTIC APPROACH

Because the liver is physiologically and anatomically diverse, no single test adequately identifies liver disease or its underlying cause. For this reason, a battery of tests must be used to assess the hepatobiliary system. Many of these tests just show liver involvement in a disease process and do not evaluate liver function. A reasonable package of screening tests recommended for an animal suspected of having hepatobiliary disease includes a complete blood count (CBC), serum biochemical profile, urinalysis, fecal analysis, and survey abdominal radiographs or ultrasonography. Results of these tests may suggest evidence of hepatobiliary disease that can be confirmed by other, more specific tests. It is important at this stage to rule out secondary hepatopathy and rule in primary liver disease because with hepatopathies secondary to other diseases, time and resources should be devoted as soon as possible to identifying and treating the underlying cause rather than investigating the liver. The need for other laboratory tests (e.g., serum bile acid [SBA], abdominocentesis, coagulation profile) is determined by each animal's history and physical examination findings.

Of the recommended screening tests for hepatobiliary disease, the serum biochemistry profile offers specific information regarding the distribution and activity or status (e.g., hyperbilirubinemia, enzyme activities) of a hepatobiliarydisorder and an estimate of the degree of functional impairment (e.g., inadequate protein synthesis, altered toxin excretion). Determining hepatic functional capacity adds a meaningful dimension to the diagnostic evaluation and permits construction of a reasonable list of differential diagnoses and tentative assignment of prognosis. It is important to remember that some hepatobiliary diseases are characterized by subtle changes in enzyme activity in association with severe functional disturbance, and some have high enzyme activities and normal functional indices. Because of the large reserve capacity of the liver, detection of global hepatic functional impairment by conventional means is not possible until there is at least 55% loss of hepatic mass. Diseases that cause acute hepatocyte loss show evidence of functional impairment more quickly than diseases with chronic hepatocyte loss, wherein the remaining hepatocytes have time to compensate. In dogs with chronic hepatitis, signs of functional impairment may not be evident until 75% of hepatic mass has been lost. The recommended serum biochemistry profile for liver disease includes, in addition to liver enzymes, albumin, urea nitrogen, bilirubin, cholesterol, and glucose concentrations, which are used to assess the ability of the liver to synthesize proteins, detoxify protein degradation products, excrete organic anions and other substances, and help maintain euglycemia, respectively. Development of automated methods for laboratory analysis has made measurement of many substances in the blood easy; these laboratory analytic methods are available at competitive prices through commercial laboratories or as point-of-care test kits or systems. For this reason, there is no excuse for excluding a multiple component serum biochemistry profile from the initial diagnostic plan for a cat or dog suspected of having hepatobiliary disease.

A sensitive, although relatively nonspecific, test of hepatobiliary function is determination of fasting and postprandial SBA concentrations. Serum bile acid concentrations are measured if there are persistent liver-specific serum biochemical abnormalities or a liver problem is suspected (e.g., microhepatia, ammonium biurate crystalluria) but results of routine diagnostic tests are inconclusive. Serum bile acids are not a helpful test of liver function in a jaundiced animal because they are also elevated in cholestasis because of decreased excretion, independent of liver function. Bile acids are not available on usual practice analyzers, but a point-of-care snap test for SBA estimation has recently become available in the United States (IDEXX Laboratories, Westbrook, ME).

Results of laboratory evaluation reflect one point in time in a spectrum of dynamic changes. If the test results are equivocal and the clinical signs are vague, sequential evaluation may be necessary to allow time for the disease to be fully expressed.

By using a combination of history, physical examination findings, and results of screening and hepatobiliary-specific laboratory tests, the clinician should be able to describe the disorder as primary or secondary (reactive) hepatopathy, active or quiescent; characterize the pattern of hepatobiliary disease as primarily hepatocellular, primarily biliary, or mixed hepatobiliary; and estimate the degree of hepatobiliary dysfunction. From this same information, an animal may be described clinically as having hepatic disease, with evidence of hepatic abnormalities such as high liver enzyme activities and hepatomegaly, or hepatic failure, in which there is a state of multiple function loss. Some primary hepatic diseases may progress to failure; most secondary hepatic diseases do not (Tables 37-1 and 38-1). Use of the term failure often inappropriately connotes a poor prognosis. If the underlying cause can be removed full recovery is possible. Most important, before an accurate prognosis can be given, a complete evaluation must be conducted, including, for most primary hepatobiliary diseases in both dogs and cats, a liver biopsy.

#### **DIAGNOSTIC TESTS**

# TESTS TO ASSESS STATUS OF THE HEPATOBILIARY SYSTEM Serum Enzyme Activities

Liver-specific serum enzyme activities are included routinely in screening serum biochemistry panels and are regarded as markers of hepatocellular and biliary injury and reactivity. Because marked hepatic disease can be present in patients with normal serum enzyme activity, finding normal values should not preclude further investigation, especially if there are clinical signs or other laboratory test results that suggest hepatobiliary disease. Increased serum activity of enzymes normally located in hepatocyte cytosol in high concentration reflects structural or functional cell membrane injury that would allow these enzymes to escape or leak into the blood. The two enzymes found to be of most diagnostic use in cats and dogs are alanine transaminase (ALT; glutamic-pyruvic transaminase [GPT]) and aspartate transaminase (AST; glutamic-oxaloacetic transaminase [GOT]). Because ALT is found principally in hepatocytes and AST (also located

within hepatocyte mitochondria) has a wider tissue distribution (e.g., in muscle), ALT is the enzyme selected to most accurately reflect hepatocellular injury. Less is known about the behavior of AST in various hepatobiliary diseases in companion animals, although some studies have indicated that AST is a more reliable indicator of liver injury in cats. Several studies have demonstrated mild to moderately high serum ALT activity (without histologic or biochemical evidence of liver injury), in addition to expected high serum activities of muscle-specific creatine kinase and AST, in dogs with skeletal muscle necrosis.

In general, the magnitude of serum ALT and AST activity elevation approximates the extent, but not the reversibility, of hepatocellular injury. Rather than clinical relevance being assigned to absolute values for ALT or AST activity (e.g., serum ALT activity of 200 IU/L is worse than 100 IU/L), the values should be assessed in terms of number of fold elevations from normal. Twofold to threefold elevations in serum ALT activity are associated with mild hepatocellular lesions, fivefold to tenfold elevations are seen with moderately severe lesions, and greater than tenfold increases suggest marked hepatocellular injury. ALT (and to a lesser extent AST) activity is also often increased by glucocorticoids in dogs, although to a lesser extent than ALP.

Serum enzyme activities that reflect new synthesis and release of enzyme from the biliary tract in response to certain stimuli are alkaline phosphatase (AP) and γ-glutamyltransferase (GGT). Bile retention (i.e., cholestasis) is the strongest stimulus for accelerated production of these enzymes. Unlike ALT and AST, AP and GGT are in low concentration in the cytoplasm of hepatocytes and biliary epithelium and are membrane-associated, so the fact that they simply leak out of damaged cells does not account for increased serum activity. Measurable AP activity is also detectable in nonhepatobiliary tissues of cats and dogs (including osteoblasts, intestinal mucosa, renal cortex, and placenta), but serum activity in healthy adult cats and dogs arises only from the liver, with some contribution by the bone isoenzyme in young, rapidly growing dogs and in kittens less than 15 weeks old. The renal form is mainly measurable in the urine, and the gut form has a very short half-life so is not usually measurable (although the steroid-induced isoenzyme of AP in dogs is believed to be an altered gut isoenzyme with a prolonged half-life). The half-life of feline AP is shorter than that of canine AP; thus serum activity is relatively lower in cats than in dogs with a similar degree of cholestasis, and, conversely, even mild elevations of AP in cats are clinically very significant. Markedly high serum AP activity of bone origin (mean total serum AP values more than fivefold higher than those in nonaffected individuals, with only the bone isoenzyme detected) was identified in certain healthy juvenile (7 months old) members of a family of Siberian Huskies (Lawler et al., 1996). This change is believed to be benign and familial and should be considered when results of serum AP activity are interpreted in this breed. A young, growing dog of any breed can have a mild increase in serum AP. Increased serum AP activity of unknown origin has also

been described in adult Scottish Terriers and is believed to be benign and possibly familial (Gallagher et al., 2006).

Certain drugs, the most common of which are anticonvulsants (specifically phenytoin, phenobarbital, and primidone) and corticosteroids, can elicit striking increases (up to hundredfold) in serum AP activity (and to a lesser extent GGT and also ALT activity) in dogs but not in cats. There usually is no other clinicopathologic or microscopic evidence of cholestasis (i.e., hyperbilirubinemia). Anticonvulsant drugs stimulate production of AP identical to the normal liver isoenzyme; GGT activity does not change. Pharmacologic levels of corticosteroids administered orally, by injection, or topically reliably provoke a unique AP isoenzyme that is separable from the others by electrophoretic and immunoassay techniques. This characteristic is useful when interpreting high total serum AP activity in a dog with subtle clinical signs suggestive of iatrogenic or naturally occurring hypercortisolism. The corticosteroid AP isoenzyme is a component of routine canine serum biochemistry profiles at several veterinary colleges and commercial laboratories. However, measurement of AP isoenzymes has been shown to be of limited usefulness either in dogs treated with phenobarbital (Gaskill et al., 2004) or in dogs with hyperadrenocorticism (Jensen et al., 1992). In the latter, it has a high sensitivity but very low specificity, so finding a low steroidinduced isoenzyme rules out hypercortisolism, but a high concentration of steroid-induced isoenzyme may be found in many disease other than hypercortisolism. Serum GGT activity rises similarly in response to corticosteroid influence but less spectacularly. Serum AP and GGT activities tend to be parallel in cholestatic hepatopathies of cats and dogs, although they are much less dramatic in cats. Simultaneous measurement of serum AP and GGT may aid in differentiating seemingly benign drug-induced effects from nonicteric cholestatic hepatic disease in dogs. Assessing serum AP and GGT activities together may also offer clues to the type of hepatic disorder in cats. Both enzymes are in low concentration in feline liver tissue compared with that in the canine liver and have short half-lives, so relatively smaller increases in serum activity, especially of GGT, are important signs of the presence of hepatic disease in cats. In cats a pattern of high serum AP activity with less strikingly abnormal GGT activity is most consistent with hepatic lipidosis (see Chapter 37), although extrahepatic bile duct obstruction (EBDO) must also be considered.

# TESTS TO ASSESS FUNCTION OF THE HEPATOBILIARY SYSTEM Serum Albumin Concentration

The liver is virtually the only source of albumin production in the body; thus hypoalbuminemia could be a manifestation of hepatic inability to synthesize this protein. Causes other than lack of hepatic synthesis (i.e., massive glomerular or gastrointestinal loss or bleeding) must be considered before ascribing hypoalbuminemia to hepatic insufficiency. Renal protein loss can be detected presumptively by routine urinalysis. Consistent identification of positive protein dip-

stick reactions, especially in dilute urine with inactive sediment, justifies further evaluation by at least measurement of random urine protein: creatinine ratio (normal ratio is <0.5 in cats and dogs). If proteinuria is ruled out, diseases that cause gastrointestinal protein loss should be considered; however, these diseases usually result in equivalent loss of globulins and thus panhypoproteinemia, although this is not invariably the case in inflammatory gastrointestinal disease wherein concurrent increase in gamma-globulins masks the gut loss. Conversely, although panhyproteinemia is reportedly not typical of hypoproteinemia of hepatic origin, globulin concentrations can be low in liver disease, particularly portosystemic shunts, because all plasma globulins except gamma globulins are made in the liver. In fact, globulin concentrations frequently are normal to increased in dogs and cats with chronic inflammatory hepatic disease. Because the plasma half-life of albumin is long in cats and dogs (8 to 10 days) and there must be loss of approximately 80% of functioning hepatocytes before hypoalbuminemia is expressed, the finding of hypoalbuminemia usually indicates severe chronic hepatic insufficiency. The exception to this is the hypoalbuminemia associated with a "negative acute phase" response in acute or acute-on-chronic inflammatory liver disease. Serum albumin can decrease when there is an increase in hepatic production of acute phase proteins in animals without hepatic insufficiency. Serum protein electrophoresis can help differentiate this condition from a true lack of hepatic function: Sevelius et al. (1995) showed that a low albumin concentration combined with a low concentration of acute phase proteins in electrophoresis indicated severe hepatic dysfunction with a poor prognosis, whereas hypoalbuminemia combined with normal or elevated acute phase proteins indicated a good prognosis. Hypoalbuminemia of any cause is unusual in cats, except in those with nephrotic syndrome. When interpreting serum protein concentrations, the clinician should remember that total protein values for young cats and dogs are lower than those for adults and that puppy serum albumin concentration is similar to that in adults, whereas kitten serum albumin concentration is lower than that in adult cats.

#### Serum Urea Nitrogen Concentration

Formation of urea as a means of detoxifying ammonia derived from intestinal sources takes place only in the liver. Despite this apparent advantage as a specific measure of hepatic function, serum urea concentration is commonly affected by several nonhepatic factors and the capacity of the liver to detoxify urea is so great that it is not noticeably reduced until severe, extensive end-stage liver disease ensues. Prolonged restricted protein intake because of complete anorexia or intentional reduction in protein intake for therapeutic purposes (e.g., chronic kidney disease; urate, cystine, or struvite urolithiasis) is the most common cause of low blood urea nitrogen (BUN) content. Prior fluid therapy and/ or marked polydipsia/poluria of nonrenal causes will also result in a decrease in BUN. As always, reference ranges should be considered for each species when interpreting

BUN values. For example, a BUN concentration of 12 mg/dl is well within normal limits for dogs but is subnormal for cats. If low BUN values are noted in a cat or dog with normal water intake and a good appetite for a diet with the appropriate protein content for the species (on a dry matter basis: 22% for dogs, 35% to 40% for cats), then the possibility of hepatic inability to convert ammonia to urea should be investigated.

#### Serum Bilirubin Concentration

Because of the large reserve capacity of the mononuclearphagocytic system and liver to process bilirubin (e.g., 70% hepatectomy will not cause jaundice), hyperbilirubinemia can occur only from greatly increased production or decreased excretion of bile pigment. Specific inborn errors of bilirubin uptake, conjugation, and excretion have not been documented in cats or dogs. Increased production of bilirubin from red blood cell destruction arises from intravascular or extravascular hemolysis and rarely from resorption of a large hematoma; hyperbilirubinemia also occurs in association with rhabdomyolysis in Greyhounds and other dog breeds. Under these circumstances in dogs, serum bilirubin concentrations are usually lower than 10 mg/dl. Values usually do not increase above 10 mg/dl unless there is a concurrent flaw in bilirubin excretion. This has been borne out clinically in studies of dogs with immune-mediated hemolytic anemia in which high liver enzyme activities are observed, even before treatment with corticosteroids, and moderately delayed bilirubin excretion has been documented. It has been proposed that cholestasis results from liver injury associated with hypoxia and in some cases due to early disseminated intravascular coagulation (DIC). Because increased production and decreased excretion of bilirubin occur in dogs with severe hemolysis, serum bilirubin concentrations therefore can be as high as 35 mg/dl. Icterus in cats with pure hemolytic disease is an inconsistent finding and mild if present; specific bilirubin concentrations associated with experimentally induced or naturally occurring hemolytic diseases in cats are not available.

Because nearly all diseases associated with hyperbilirubinemia in cats and dogs are characterized by a mixture of conjugated and unconjugated bilirubinemia, quantifying the two fractions by use of van den Bergh's test achieves little in discriminating primary hepatic or biliary disease from nonhepatobiliary disease in a clinical setting. This lack of benefit in using van den Bergh's test may relate to the time between onset of illness and examination, which is usually at least several days. Under conditions of acute massive hemolysis, the total serum bilirubin concentration may consist primarily of the unconjugated form initially. As hemolysis continues, the liver is able to take up and conjugate bilirubin, accounting for a combination of unconjugated and conjugated bilirubin.

Because red blood cell membrane changes are often a component of many primary hepatobiliary disorders, accelerated red blood cell destruction often contributes to hyperbilirubinemia. In such cases, there is strong clinicopathologic evidence of cholestasis (high serum AP and GGT activities with moderate to high ALT activity), and if there is anemia, it is mild and poorly regenerative. Hyperbilirubinemia is attributed primarily to hemolysis when there is moderate to marked anemia with strong evidence of regeneration (except in the first 1 to 3 days, when the response is less regenerative) and minimal changes in serum markers of cholestasis.

#### Serum Cholesterol Concentration

Total cholesterol concentration is included in serum chemistry profiles by many commercial laboratories but affords useful information for only a limited number of hepatobiliary diseases. High total cholesterol values are observed in cats and dogs with severe intrahepatic cholestasis involving bile ducts or EBDO because of impaired excretion of free cholesterol into the bile and subsequent regurgitation into the blood. Low total serum cholesterol concentrations have been noted in dogs with chronic severe hepatocellular disease and frequently in cats and dogs with congenital portosystemic shunts (PSS). It has been speculated that hypocholesterolemia is a sign of markedly altered intestinal absorption of (and increased use of) cholesterol for bile acid synthesis when the enterohepatic recirculation of bile acids is disturbed, as occurs with PSS. In other hepatobiliary diseases of cats and dogs, the total cholesterol values vary considerably within the reference range. Normal values in 4-week-old kittens are higher than those for adults; 8-week-old puppy reference ranges are the same as those for adults.

#### **Serum Glucose Concentration**

Hypoglycemia is an unusual event associated with hepatobiliary disease in dogs and especially in cats. Lost capacity to maintain normal serum glucose concentrations occurs in animals with acquired chronic progressive hepatobiliary disease when 20% functional hepatic mass or less is remaining. This inability to maintain normal serum glucose concentrations is presumably caused by the loss of hepatocytes with functioning gluconeogenic and glycolytic enzyme systems and impaired hepatic degradation of insulin. Hypoglycemia is often a near-terminal event in dogs with chronic progressive hepatobiliary disease. In striking contrast is the frequent observation of hypoglycemia in dogs with congenital PSS, particularly small-breed dogs. In PSS hypoglycemia may be due to an increase in circulating insulin concentration caused by reduced first pass metabolism in the liver, as observed in humans, but this has never been investigated in dogs. Hypoglycemia is also common as a paraneoplastic syndrome in dogs with large hepatocellular carcinomas and can be associated with production in insulin-like growth factor by the tumour (Zini et al., 2007). In either case, if hypoglycemia is identified and confirmed by repeating the test using sodium fluoride tubes if necessary, and if nonhepatic causes (functional hypoglycemia, sepsis, insulinoma, or other neoplasm producing an insulin-like substance, Addison's disease; see Chapter 53) are excluded, a primary hepatic tumor (e.g., hepatocellular carcinoma), a PSS, or severe generalized hepatopathy is suspected.

#### **Serum Electrolyte Concentrations**

Serum electrolyte determinations facilitate supportive care of cats and dogs with hepatobiliary disease but give no particular hints as to the character of the disorder. The most common abnormality is hypokalemia, which is attributed to a combination of excessive renal and gastrointestinal losses, reduced intake, and secondary hyperaldosteronism in dogs and cats with severe chronic hepatobiliary disease. Metabolic alkalosis, presumptive evidence of which might be abnormally high serum total carbon dioxide content confirmed by blood gas analysis, is usually caused by overzealous diuretic therapy in dogs with chronic hepatic failure and ascites. Hypokalemia and metabolic alkalosis potentiate each other and may also worsen signs of hepatic encephalopathy (HE) by promoting persistence of readily membrane-diffusible ammonia (NH<sub>3</sub>).

#### Serum Bile Acid Concentrations

Recent validation of rapid, technically simple methods for SBA analysis in cats and dogs has provided a sensitive, variably specific test of hepatocellular function and the integrity of the enterohepatic portal circulation. "Primary" bile acids (i.e., cholic, chenodeoxycholic) are synthesized only in the liver, where they are conjugated with various amino acids (primarily taurine) before secretion into the bile. Bile is stored in the gallbladder, where it is concentrated until, under the influence of cholecystokinin, it is released into the duodenum. After facilitating fat absorption in the small intestine, the primary bile acids are efficiently absorbed into the portal vein and returned to the liver for reuptake and resecretion into the bile. A small percentage of primary bile acids that escapes resorption is converted by intestinal bacteria to "secondary" bile acids (i.e., deoxycholic, lithocholic), some of which are also resorbed into the portal circulation. Absorption of bile acids by the intestine is extremely efficient, but hepatic extraction from portal venous blood is not. This accounts for small concentrations of cholic, chenodeoxycholic, and deoxycholic acids that are released into the peripheral blood of healthy cats and dogs in the fasting state (total <5 µmol/L by enzymatic method and 5 to 10 µmol/L by radioimmunoassay [RIA]). During a meal a large load of bile acids is delivered to the intestine and portal circulation for recycling; postprandial values in normal dogs and cats may increase up to threefold to fourfold over fasting values (15 µmol/L with the enzymatic method for cats and dogs; 25 μmol/L with the RIA method for dogs). Normal values for juvenile animals are similar to adult reference ranges. Abnormally high fasting and/or postprandial SBA concentrations reflect disturbance in hepatic secretion into the bile or at any point along the path of portal venous return to the liver and hepatocellular uptake. Low SBA concentrations may be attributable to small intestinal (ileal) malabsorption of bile acids but might be difficult to interpret because both fasting and postprandial SBA concentrations may not be measurable in healthy animals.

The standard way to assess SBA concentrations is outlined in Box 36-1. Collective experience indicates that the

BOX 36-1

Summary of Techniques for Bile Acid Stimulation Test and Postprandial Ammonia Challenge Test

#### **Bile Acid Stimulation Test**

Collect a 3-ml blood sample in a serum tube after the animal was fasted for 12 hours.

Feed a small amount of food that is normal in fat content (approximately 27% fat [dry matter basis] in dogs).

Collect another 3-ml blood sample in a serum tube 2 hours after the meal.

#### Postprandial Ammonia Challenge Test

Collect a 3-ml blood sample after the animal was fasted for 12 hours.

Feed an amount of food corresponding to 25% of the dog's daily metabolic energy requirement.

Collect another 3-ml blood sample in a serum tube 6 hours after the meal.

likelihood of precipitating an episode of HE during this part of the test is extremely low, even in predisposed animals. After the serum is harvested, the samples may be refrigerated for several days or frozen almost indefinitely before assay. The stability of the blood sample is one of the major advantages over the much more labile serum ammonia test.

Studies of SBAs have confirmed their value in detecting clinically relevant hepatobiliary disease requiring definitive diagnostic testing in cats and dogs, especially in anicteric animals with equivocal clinical signs and unexplained high liver enzyme activity. There continues to be controversy as to whether a fasting or postprandial value alone is sufficient or whether fasting and postprandial measurements are required. If only one sample can be obtained (and the animal will eat or can tolerate being force-fed a small meal), the postprandial value is most useful to determine the presence or absence, but not the type, of clinically relevant hepatobiliary disease in most cats and dogs. Current recommendations state that for animals suspected of having acquired hepatobiliary disease, biopsy is needed when postprandial SBA concentration using the enzymatic method exceeds 20 μmol/L in cats and 25 μmol/L in dogs, although other authors (particularly in the United Kingdom) suggest that SBA between 20 and 40 µmol/L in dogs represents a grey area (Hall et al., 2005). Elevations in this region have been seen with secondary hepatopathies (particularly hyperadrenocorticism) and with small intestinal bacterial overgrowth because of reduced hepatic clearance of deconjugated bile acids. Therefore the authors would recommend a liver biopsy with a higher cut-off for postprandial bile acids of 40 μmol/ L. No pattern of preprandial and postprandial values is pathognomonic for any particular hepatic disorder, although it is safe to make certain generalizations. Magnitude of elevation above 20  $\mu$ mol/L in cats and 25  $\mu$ mol/L in dogs roughly correlates with the severity, but not the reversibility, of the hepatobiliary disorder, although with PSS, the magnitude of elevation does not correlate with the degree of shunting or severity of clinical signs. The change between the fasting value and the postprandial value likely corresponds to portosystemic shunting, either microscopic (intrahepatic) or macroscopic. There is so much overlap in fasting and postprandial SBA patterns among primary hepatobiliary diseases that no particular statement can be made regarding the specific causative hepatobiliary disease. Occasionally, fasting SBA levels are higher than postprandial levels, which signifies nothing more than occasional, normal, spontaneous gallbladder contraction in fasting. In general, secondary hepatic diseases cause more modest hepatobiliary dysfunction (SBA values <100  $\mu$ mol/L).

For the diagnosis of congenital PSS, fasting and postprandial SBA determinations are recommended to enhance detection ability because it is relatively common for fasting values to be well within normal limits and for postprandial values to be as high as tenfold to twentyfold higher than normal postprandial values.

Now that simplified methods for SBA measurement have been developed (i.e., enzymatic, RIA) and are accessible, determination of total SBA has become a convenient, practical test of hepatobiliary function in cats and dogs. Some reference laboratories use an adapted enzymatic method, a commercial enzymatic kit (Enzabile; Nyegaard and Co., Olso, Norway), or a commercial RIA (Conjugated Bile Acids Solid Phase Radioimmunoassay Kit 125I; Becton Dickinson, Orangeburg, N.Y.). Each yields comparable diagnostic results, although the sample size needed for the RIA assay is quite small (50 µl) compared with the enzymatic method (400 to 500 µl). Because the measurement of fasting and postprandial SBA concentrations assesses the same functions as the ammonium chloride (NH<sub>4</sub>Cl) tolerance test without potentially dangerous consequences, it is the preferred test. As with any specially requested test, the laboratory chosen should use methods verified for clinical use in the target species and be able to provide reference ranges.

A benchtop "SNAP" test for bile acids has recently become available from IDEXX Laboratories (see http://www.idexx.com/animalhealth/analyzers/vetlabnotes/2005snapreader.jsp). The disadvantage of the SNAP test is that it has a low cut-off, which means that it does not differentiate secondary from primary hepatobiliary disease.

Several factors may affect SBA values and therefore their interpretation. One aspect of the SBA challenge test that has not been standardized is the feeding step. The ideal quantity and composition of the test meal have not been determined. Size of the test meal and therefore consumption of the entire meal or only part of the meal may affect gastric emptying. Delayed gastric emptying could cause the peak SBA concentration to occur more than 2 hours later. Hastened or delayed intestinal transit time or the presence of intestinal disease (especially of the ileum) may also impede and blunt peak absorption of the test meal. It is likely that fat content of the test meal is important because fat is the primary stimulus for the small intestinal mucosa to secrete cholecystokinin, which

causes gallbladder contraction. Expulsion of bile during periodic physiologic gallbladder contraction between meals may complicate interpretation of the fasted sample result. Lipemia of the sample can seriously affect the validity of the test, particularly on heparinized blood. For this reason, it is far preferable to use serum, both for the external samples and for the snap test.

Several questions remain to be answered regarding the clinical use of SBA measurement in cats and dogs. Investigation of individual SBA profiles in cats and dogs with various hepatobiliary diseases has provided interesting information but no clear and specific profile for any one disease. Can sequential SBA values be used to more precisely monitor a cat's or dog's progress? Until this and other questions are answered, use of SBA analysis is limited to measuring total serum values as a sensitive and relatively specific screening test for the presence or absence of clinically significant hepatobiliary disease. Additional diagnostic testing must always follow to identify the specific cause.

#### **Urinary Bile Acid Concentrations**

Determination of bile acids accumulating in urine over time can be used to assess hepatobiliary function. Urine bile acids are believed to reflect average serum bile acid concentrations during the interval of urine formation. Expression of urine bile acid concentrations as a ratio with the urine creatinine concentration eliminates the influence of urine concentration and flow. Random urine sampling for bile acid determination does not require attending to the timing of an enterohepatic challenge or obtaining a sample after withholding food. In recent studies urinary bile acid concentrations were increased in dogs and cats with hepatobiliary disease and portosystemic vascular anomalies, compared with dogs and cats with nonhepatic disorders (except for hepatic neoplasia in dogs; Balkman et al., 2003; Trainor et al., 2003). The urine nonsulfated bile acid: creatinine ratio and the urine sulfated plus nonsulfated bile acid: creatinine ratio positively correlated with serum bile acid test results and had similar overall diagnostic performance and substantially higher (dogs) or similar (cats) specificity, compared with the serum bile acid test, and are recommended. The urine sulfated bile acid: creatinine ratio had lower sensitivity in dogs and cats, compared with the serum bile acid test.

#### **Plasma Ammonia Concentration**

One test that is not included in a standard screening battery of tests but is available through reference or human hospital laboratories is plasma ammonia concentration. Fasting plasma ammonia can be measured in any cat or dog with historic or physical examination findings suggestive of HE. Signs of HE (see Box 35-2), whether they have a congenital or acquired basis, appear the same. Quantifying plasma ammonia concentration not only can confirm HE, although normal fasting values in animals with hepatobiliary disease are relatively common, but can also provide baseline data and help in evaluating response to treatment. However, SBA

values (particularly postprandial) provide very similar information. Some investigators have suggested that arterial ammonia concentrations may more accurately represent blood ammonia status in dogs with hepatobiliary disease than venous measurements because skeletal muscle can metabolize ammonia. High plasma ammonia concentration usually indicates reduced hepatic mass available to process ammonia and/or the presence of portosystemic shunting, which disrupts presentation of ammonia to the liver for detoxification. However, ammonia is very labile in the blood sample and, for example, can be falsely elevated if the blood sample is taken in an environment contaminated with urine. Sample handling has to be undertaken with caution, and some benchtop analyzers are inaccurate, particularly in the moderately elevated range. For these reasons, SBAs are often a preferred test. The exception to this would be an animal with suspected hepatic encephalopathy and concurrent cholestasis. As outlined in the preceding paragraphs, bile acid concentrations will be high in cholestasis (because they are excreted in the bile) independent of any reduction in liver function or shunting. Measuring blood ammonia in these circumstances will give useful additional information about potential shunting and HE.

In a recent study the 12-hour fasting plasma ammonia concentration had higher sensitivity and specificity than the 12-hour fasting bile acid concentration for detecting portosystemic shunting in a general population of dogs and in dogs with liver disease (Gerritzen-Bruning et al., 2006). However, a bile acid stimulation test (fasting and 2-hour postprandial bile acid) has a much higher sensitivity for detecting PSS than a single fasting bile acid, and a single postprandial bile acid concentration is likely as sensitive as a fasting ammonia concentration, although the authors did not test this.

Although reference ranges vary among laboratories, fasting plasma ammonia values for normal dogs are typically 100 mg/dl or less and 90 mg/dl or less for normal cats. At least 6 hours of fasting should precede sample collection. Samples must be collected into iced ammonia-free heparinized tubes and spun immediately in a refrigerated centrifuge. Plasma must be removed within 30 minutes so that values will not be spuriously elevated by hemolysis because red blood cells contain two to three times the ammonia concentration of plasma. To obtain accurate values, feline plasma can be frozen at -20°C and assayed within 48 hours; canine plasma must be assayed within 30 minutes.

If signs are compatible with HE at the time of sample collection, a single fasting sample will suffice. If there are no signs of HE and results of other tests are equivocal, a post-prandial challenge test may be performed (see Box 36-1). The older ammonium chloride challenge tests (either oral or rectal) are contraindicated because of the significant potential for either test to trigger a severe encephalopathic crisis in the patient. The postprandial ammonia test is a safer test and has a 91% sensitivity for portosystemic shunting but only a 31% sensitivity for diffuse hepatocellular disease (Walker et al., 2001).

#### **Plasma Protein C Activity**

Plasma protein C activity was recently evaluated as a marker of hepatobiliary disease in dogs. Protein C is an anticoagulant protein that is synthesized in the liver and circulates as a plasma zymogen. Low protein C activity has been associated with thrombotic disorders in humans and animals. Low protein C activity has also been documented in dogs with acquired and congenital hepatobiliary disorders, and dogs with PSS appear to develop the lowest protein C activity. In a recent study by Toulza et al. (2006), protein C acivity was significantly lower in dogs with congenital or acquired portal systemic shunts, compared with dogs without PSS. Plasma protein C activity improved or normalized after surgery for the shunt. These findings suggest that plasma protein C activity reflects the adequacy of hepatoportal perfusion in dogs and that protein C activity may prove useful as a means to monitor improvement of hepatic-portal perfusion after ligation of portosystemic vascular anomalies. Plasma protein C activity may also help differentiate dogs with intrahepatic portal vein hypoplasia from those with portal systemic vascular anomaly (plasma protein C activity ≥70% versus <70%, respectively).

#### **URINALYSIS**

Common findings in urinalysis consistent with hepatobiliary disease include excessive bilirubinuria in a nonanemic dog (2+ in urine of specific gravity <1.025), presence of bilirubin in the urine of cats, and ammonium biurate crystalluria in properly processed urine specimens (Fig. 36-1). In dogs excessive bilirubinuria may precede the onset of hyperbilirubinemia and jaundice. Small numbers of bilirubin crystals may be found in concentrated urine specimens from normal dogs and ammonium biurate crystals are also occasionally found in normal animals and also in Dalmatian dogs with a defect in urate metabolism (see Chapter 46) and therefore are not pathognomonic for PSS. Hyperammonemia combined with excess uric acidemia from diminished hepatic

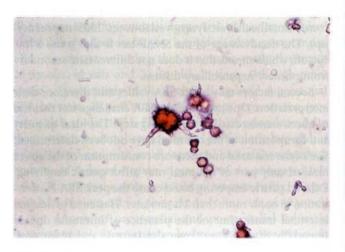

FIG 36-1
Ammonium biurate crystals in the urine of a dog with a congenital portosystemic shunt.

conversion to allantoin exceeds the renal threshold and favors precipitation of crystals, especially in alkaline urine. Their presence in the urine may fluctuate, but alkalinizing the urine specimen with a few drops of sodium or potassium hydroxide may increase the likelihood of identifying ammonium biurate crystals during sediment examination.

Measurement of urinary urobilinogen by dipstick analysis has traditionally been used to assess the patency of the extrahepatic biliary system. So many factors influence detection of urobilinogen in the urine (e.g., intestinal flora and transit time, renal function, urine pH and specific gravity, exposure of the urine specimen to light) that the test is now considered to be of minimal value in diagnosing EBDO. If urine samples are obtained serially and processed properly, repeated absence of urobilinogen suggests, but is not diagnostic of, complete EBDO.

Consistently dilute urine (specific gravity as low as 1.005) may be a feature of congenital and acquired PSS and severe hepatocellular diseases because of the associated polydipsia/polyuria and hypercortisolism, as discussed in Chapter 35. Urine specific gravity must also be interpreted in light of concurrent drug therapy, such as administration of diuretics, corticosteroids, or anticonvulsants.

#### **FECAL EVALUATION**

Fecal specimen analysis rarely provides useful information in the evaluation of a dog or cat with suspected hepatobiliary disease, except for a change in appearance associated with two specific conditions. Absence of fecal pigment (acholic feces; see Fig. 35-6) and steatorrhea are consequences of chronic complete EBDO, and dark, orange-colored feces reflect increased bilirubin production and excretion after marked hemolysis or rhabdomyolysis. It should also be noted that gastrointestinal ulceration is a serious and important complication of portal hypertension, particularly in dogs (see Chapter 39), so the clinician should always be alert to the development of melena in a dog with chronic liver disease.

#### ABDOMINOCENTESIS/FLUID ANALYSIS

If abdominal fluid is detected during physical examination, abdominal radiography, or ultrasonography, a sample must always be obtained for analysis. For moderate to large volume effusion, simple needle paracentesis is sufficient to obtain 5 to 10 ml of fluid for gross inspection; determination of protein content; cytologic evaluation; and, in selected cases, special biochemical analysis. Larger volumes are removed using an over-the-needle-style catheter with extension tubing or a needle with attached tubing (E-Z infusion set) if clinical signs secondary to fluid accumulation are present (e.g., dyspnea) or if removal of abdominal fluid is part of the treatment (e.g., bile peritonitis). Removal of a significant volume of abdominal fluid for clinical reasons should be avoided unless it is absolutely necessary because doing so often causes a precipitous decrease in serum protein concentrations in animals with liver disease owing to the inability of the liver to replace proteins removed in the fluid. It is

preferable in cases other than peritonitis to remove fluid gradually, using diurctics. In cases in which large volume fluid removal is necessary (e.g., for dyspnea), concurrent administration of fresh frozen plasma or a colloid solution is essential. In dogs with chronic hepatic failure and sustained intrahepatic portal hypertension, abdominal fluid is usually a modified transudate with moderate nucleated cell count and protein content (Table 36-1). A pure transudate with low cell count (<2500 cells/µl) and protein concentration (<2.5 g/dl), and a clear, minimally colored appearance is found when the dog is hypoproteinemic. Abdominal fluid in dogs with intrahepatic postsinusoidal venous obstruction (e.g., venoocclusive disease) or posthepatic venous obstruction (e.g., any cause of right-sided heart failure) can be any color but is typically red- or yellow-tinged and is classified as a modified transudate. Feline infectious peritonitis fluid and neoplastic effusions are also commonly classified as modified transudates or nonseptic exudates. Bile peritonitis also results in an exudate, which is initially sterile but can become septic with time. With neoplasia, effusions can occasionally be chylous or even hemorrhagic, and the latter can also be seen in amyloidosis as a result of rupture of the liver capsule. Reactive mesothelial cells can be mistaken for neoplastic cells, emphasizing the need for experience in evaluating cytologic specimens. Exudates have high cell counts (>20,000 cells/µl) and protein content (>2.5 g/dl) and, on the basis of whether the inflammatory cells look toxic or contain ingested bacteria, are further classified as septic or nonseptic. Fluid analysis provides additional clues to the origin of hepatobiliary disease and must not be overlooked. A guide to interpreting fluid analysis results is given in Table 36-1.

#### **COMPLETE BLOOD COUNT**

There are few changes in blood cells that suggest hepatobiliary disease. Most are changes in erythrocytes associated with fragmentation or changes in cell size or membrane composition (Fig. 36-2). Microcytosis (mean cell volume [MCV] <60 fl in canine breeds other than the Japanese Akita or Shiba Inu) with normochromia or slight hypochromia (mean cell hemoglobin concentration: 32 to 34 g/dl) is a rather common finding in dogs with congenital PSS (≥60%); it is less common in cats with congenital PSS (≤30%). Most affected animals are not anemic. The cause of microcytosis, which has also been observed with less frequency in dogs with chronic hepatic failure and acquired PSS, is chelation of iron within the liver rather than absolute iron deficiency; therefore iron supplementation does not help. However, the change in the size of red blood cells is reversible upon restoration of portal blood flow. If anemia is also present, microcytosis must be distinguished from anemia of inflammatory disease, which can occasionally cause small red blood cells and relative iron deficiency, or from iron deficiency anemia associated with chronic gastrointestinal blood loss (see Chapter 83).

Strongly regenerative anemia, with macrocytosis, high reticulocyte count, and normal to slightly increased serum

TABLE 36-1

Characteristics of Abdominal Effusion in Hepatobiliary Disease

	APPEARANCE	CELL COUNT	PROTEIN CONTENT	SPECIFIC GRAVITY	EXAMPLE(S)
Pure transudates	Clear, colorless	<1500/μΙ	<2.5 g/dl	<1.016	Chronic hepatic failure with marked hypoalbuminemia
Modified transudates	Serosanguineous, amber	<7000/μΙ	≥2.5 g/dl	1.010-1.031	Chronic hepatic failure, right-sided heart failure, pericardial disease, caval syndrome, Budd-Chiari-like syndrome, intrahepatic portal vein hypoplasia, chronic portal vein thrombosis, feline infectious peritonitis [some cases], neoplasia (some cases]
<b>Exudates</b> Septic	Cloudy; red, dark yellow, green	>7000/μl	≥2.5 g/dl	1.020-1.031	Perforated duodenal ulcer, bile peritonitis (fluid bilirubin concentration exceeds serum bilirubin concentration)
Nonseptic	Clear; red, dark yellow, green	>7000/μl	≥2.5 g/dl	1.017-1.031	Feline infectious peritonitis, neoplasia with serosal involvement, ruptured hemangiosarcoma, early bile peritonitis
Chylous effusions	Opaque, white to pink ("strawberry milkshake")	Variable; usually 1000- 10,000/μl	Variable; 2.5- 6.5 g/dl	1.030-1.032	Neoplasia (some cases); diseases obstructing lymphatic drainage
Hemorrhagic effusions	Red	Variable; usually 1500 to 1000/µl	Usually >3.0 g/dl	<1.013	Neoplasia (some cases); amyloidosis with hepatic capsule rupture; ruptured hemangiosarcoma

protein concentration in a jaundiced dog, especially if spherocytes are also identified, indicates hemolytic anemia and increased bilirubin formation as the cause of jaundice. Cats and dogs with hemolytic anemia typically also have high serum liver enzyme activities and bile acid concentrations, pointing to hepatic consequences developing secondary to the effects of marked hemolysis, such as hypoxia and thromboembolism.

Certain red blood cell morphologic changes are consistent with serious hepatobiliary disease and are related to alterations in lipoprotein metabolism and irregularities in red blood cell membrane structure. Acanthocytes, leptocytes, and codocytes (target cells) are good examples (see Fig. 36-2). Poikilocytosis of unknown pathogenesis is a consistent finding in cats with congenital PSS and occasionally with other hepatobiliary diseases; cats with chronic hepatobiliary disease frequently have Heinz bodies in their red blood cells. Fragmented red blood cells or schistocytes constitute an expected finding in animals with DIC; hemangiosarcoma is considered when an inappropriate number of

nucleated red blood cells is also detected. Mild to moderate nonregenerative anemia is common in cats with many different illnesses, including those of the hepatobiliary tract.

Few changes in the leukon are expected in cats or dogs with hepatobiliary disease, except when an infectious agent is present as the initiating event (histoplasmosis, bacterial cholangitis, or leptospirosis in dogs); where there is concurrent pancreatitis, which is particularly common in cats (see Chapter 40); or when infection has complicated a primary hepatobiliary disorder (e.g., gram-negative sepsis in a dog with cirrhosis, septic bile peritonitis). Neutrophilic leukocytosis is likely in such cases, whereas pancytopenia is typical of disseminated histoplasmosis and severe toxoplasmosis in cats and of early infectious canine hepatitis.

#### **COAGULATION TESTS**

Clinically relevant coagulopathies are unusual in cats and dogs with hepatobiliary disease except for those with acute hepatic failure (including acute hepatic lipidosis in cats or hepatic lymphoma in both species), complete EBDO, or

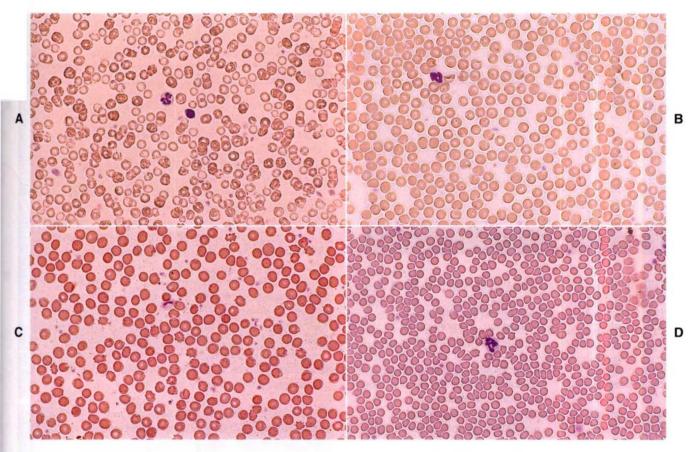

FIG 36-2

Erythrocyte morphologic changes often associated with hepatobiliary disease in cats and dogs (Wright-Giemsa stain). **A,** Microcytic red blood cells (mean corpuscular volume [MCV] = 45 fl) from dog with congenital portosystemic shunt; compare the microcytic red blood cells with the size of a nearby normal small lymphocyte 6 to 9  $\mu$ m in diameter. **B,** Normal canine red blood cells (MCV = 70 fl) for comparison. **C,** Acanthocytes from dog with severe chronic hepatic passive congestion. **D,** Poikilocytes from cat with cholangitis.

active DIC. It is more common to have subtle prolongation of activated partial thromboplastin time (APTT; 1.5 times normal), abnormal fibrin degradation products (10 to 40 or higher), and variable fibringen concentration (<100 to 200 mg/dl) in cats and dogs with severe parenchymal hepatic disease. Elevated D-dimers are common in patients with liver disease and do not always indicate DIC in these cases. It has been proposed that nonspecific elevation can occur in liver disease as a result of reduced clearance by the liver. Platelet numbers may be normal or low; mild thrombocytopenia (130,000 to 150,000 cells/µl) is usually associated with splenic sequestration or chronic DIC. More severe thrombocytopenia (100,000 cells/1) is expected in acute DIC or decompensated chronic DIC. Some animals with severe hepatic disease and relatively unremarkable routine coagulation test results have high serum activity of proteins induced by vitamin K antagonism (PIVKA) that could impart bleeding tendencies. Primary or metastatic cancer of the liver could also cause coagulopathy unrelated to loss of hepatocellular ability to make or degrade coagulation proteins.

A summary of laboratory tests for cats and dogs with hepatobiliary disease and interpretation of their results is given in Table 36-2.

#### **DIAGNOSTIC IMAGING**

#### **SURVEY RADIOGRAPHY**

Radiographic evaluation of the abdomen is used to complement physical examination findings and to confirm suspicions regarding the character and location of the hepatobiliary disease suggested by results of clinicopathologic examination. Survey radiographs provide subjective information regarding the size and shape of the liver (see Table 35-1). Optimally, the animal should have an empty gastrointestinal tract at the time the radiographs are obtained. In the normal dog and cat in right lateral recumbency, the gastric axis is parallel to the ribs at the tenth intercostal space, and the caudoventral border of the liver (the left lateral liver lobe) appears sharp; the image is made possible by the con-

**TABLE 36-2** 

Summary of First- and Second-Line Clinicopathologic Tests Useful in the Diagnosis of Hepatobiliary Disease

SCREENING TEST	PRINCIPLE EXAMINED	COMMENTS
Serum ALT, AST	Integrity of liver cell membranes;	Degree of increase roughly correlates with number of
activities	escape from cells	hepatocytes involved but not severity of disease
Serum AP, GGT activities	Reactivity of biliary epithelium to various stimuli; increased synthesis and release	Increase associated with intrahepatic or extrahepatic cholestasis or drug effect (dogs only): corticosteroids, anticonvulsants (AP only, not GGT)
Serum albumin concentration	Protein synthesis	Rule out other causes of low concentration (glomerular or intestinal loss); low value indicates ≥80% overall hepatic function loss or negative acute phase response
Serum urea concentration	Protein degradation and detoxification	With low values, rule out prolonged anorexia; dietary protein restriction; severe PU/PD; urea cycle enzyme deficiency (rare); congenital PSS; severe, acquired chronic hepatobiliary disease
Serum bilirubin concentration	Uptake and excretion of bilirubin	Rule out marked hemolysis first; if PCV is normal, intrahepatic or extrahepatic cholestasis is present
Serum cholesterol concentration	Biliary excretion, intestinal absorption, integrity of the enterohepatic circulation	High values compatible with severe cholestasis of any kind; low values suggest congenital PSS; anticonvulsant drug-induced change; severe, acquired chronic hepatobiliary disease; or severe intestinal malassimilation
Serum glucose concentration	Hepatocellular gluconeogenic or glycolytic ability; insulin and other hormone metabolism	Low values indicate severe hepatocellular dysfunction, PSS, or presence of a primary liver tumor
Plasma ammonia concentration	Integrity of the enterohepatic circulation, hepatic function and mass	High fasting or postprandial values suggest congenital or acquired PSS or acute hepatocellular inability to detoxify ammonia to urea (massive necrosis)
Serum bile acid concentrations	Integrity of the enterohepatic circulation, hepatic function and mass	High fasting or postprandial values compatible with hepatocellular dysfunction, congenital PSS, or loss of hepatic mass. Elevated in cholestasis independent of hepatocellular dysfunction or shunting so rule this out first
Coagulation profile	Hepatocellular function, adequacy of vitamin K absorption and stores	Abnormal values may indicate marked hepatocellular dysfunction, acute or chronic DIC, complete EBDO

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; AP, alkaline phosphatase; GGT, Yglutamyltransferase; PU/PD, polyuria/polydipsia; PSS, portosystemic shunting; PCV, packed cell volume; DIC, disseminated intravascular coagulation; EBDO, extrahepatic bile duct abstruction.

trasting fat-filled falciform ligament (Fig. 36-3). In dog breeds with narrow, deep chests, the entire liver shadow may be contained within the caudal rib cage. In dogs with wide, shallow thoracic conformation, the liver may extend slightly beyond the costal arch. In the ventrodorsal view the borders of the liver are defined by the cranial duodenum and the gastric fundus; in this view the gastric shadow is perpendicular to the spine. This view is less useful for assessing liver size unless it is markedly and asymmetrically enlarged. Immature animals have a relatively larger liver than do adults. The gallbladder and extrahepatic biliary tree are not visible separately radiographically in healthy animals.

Survey radiography is of minimal to no benefit if there is moderate to marked abdominal effusion because the similar radiographic opacities of the liver and fluid preclude distinction of liver size and shape except by indirect assessment (e.g., malposition of a gas-filled stomach and duodenum; Fig 36-4). However, because abdominal fluid increases ultraso-

nographic contrast, this is the imaging modality of choice in animals with ascites. Poor abdominal detail in emaciated or very young animals lacking abdominal fat stores also makes detection of subtle hepatic changes difficult.

In cats and dogs with generalized hepatomegaly, the liver extends beyond the costal arch; it causes displacement of the gastric axis and pylorus caudally and dorsally in the lateral projection and shifting of the gastric shadow caudally and to the left in the ventrodorsal view (see Fig 36-3). In addition, the edges of the liver in the lateral view may appear rounded (see Fig. 36-3). Occasionally, the spleen and liver cannot be differentiated when they are in direct contact, as seen in the right lateral view. A ventrodorsal view would help to determine the size, shape, and position of each organ. Increased intrathoracic volume associated with deep inspiration, severe pleural effusion, or overinflation of the lungs may result in caudal displacement of the liver, giving the erroneous impression of hepatomegaly using other radiographic criteria.

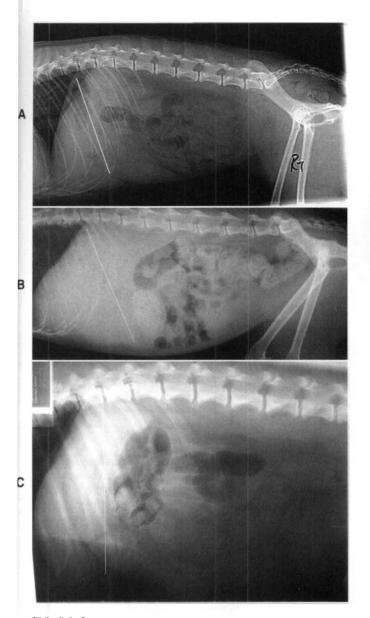

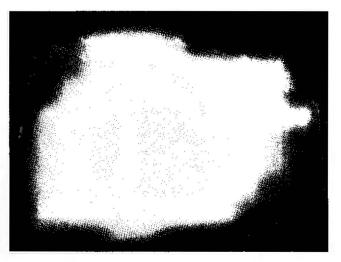

FIG 30-3

Lateral abdominal radiographs demonstrating gastric axis (white line) as an indication of liver size. A, Lateral abdominal radiograph of a normal cat with normal liver size. B, Lateral abdominal radiograph of a cat with diffuse hepatic amyloidosis demonstrating hepatomegally and caudal displacement of the gastric axis. C, Lateral abdominal radiograph of a middle-aged English Springer Spaniel with cirrhosis demonstrating microhepatica and cranial displacement of the gastric axis. (Radiographs courtesy the diagnostic imaging department, The Queen's Veterinary School Hospital, University of Cambridge.)

Because the liver may be contained entirely within the rib cage in normal cats and dogs, microhepatia is more difficult to recognize than hepatomegaly. Changes in the angle of the gastric fundus in the right lateral projection (see Fig. 36-3) could indicate a small hepatic shadow if the angle is more upright or perpendicular to the spine and especially if the stomach seems rather close to the diaphragm. The liver may

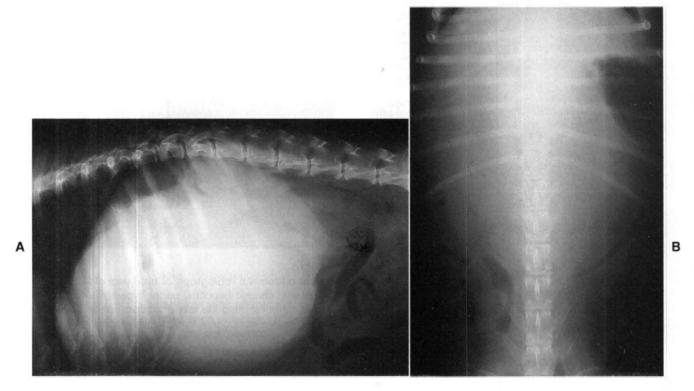

Lateral abdominal radiograph of an 8-year-old Bearded Collie with chronic hepatitis, portal hypertension, and ascites demonstrating the loss of abdominal detail associated with free abdominal fluid, which renders radiography unhelpful. (Radiograph courtesy the diagnostic imaging department, The Queen's Veterinary School Hospital, University of Cambridge.)

also seem small in animals with traumatic diaphragmatic hernia and herniation of liver lobes into the thorax or in those with congenital peritoneopericardial hernia.

Focal hepatic enlargement is indicated by displacement of organs adjacent to the affected lobe. The most common radiographically detectable focal hepatic enlargement is that of the right lateral lobe, an example of which is shown in Fig. 36-5. In this case the body and pyloric regions of the stomach are shifted dorsally (lateral view) and to the patient's left (ventrodorsal view); the gastric fundus remains in normal position. Shifting of the stomach to the left is normal in cats and should not be mistaken for right hepatomegaly. If the left lateral lobe or lobes are enlarged, the gastric fundus moves to the left and caudally; the lesser curvature of the stomach may appear indented. Primary or metastatic neoplasia, hyperplastic or regenerative nodules, and cysts most commonly account for focal hepatic enlargement or for irregular liver margins without enlargement. If the gallbladder is massively enlarged because of EBDO, it may mimic a right cranial abdominal mass or an enlarged, rounded liver lobe. Changes in hepatic radiographic opacity are rare and are usually associated with hepatic or biliary tract infection caused by gas-forming bacteria (patchy and/or linear areas of decreased opacity) or mineralization (focal or diffuse spots of mineralization or mineralized biliary calculi).

With the advent of ultrasonography, contrast radiographic procedures are seldom needed to confirm the presence of hepatic masses, cholelithiasis, EBDO, congenital PSS, and other structural diseases. The contrast study that is still necessary to localize some types of congenital PSS and is achievable in private practice is portal venography. Acceptable approaches for this technique are splenoportography,

Lateral (A) and ventrodorsal (B) abdominal radiographs of a 9-year-old spayed female mixed-breed dog with a hepatocellular carcinoma enlarging the right lateral liver lobe. The dog was also severely hypoglycemic.

operative mesenteric portography, and operative splenoportography. The two operative procedures require general anesthesia and a small abdominal incision; however, little sophisticated equipment is needed, and the procedures are associated with few complications. A 22-gauge catheter is placed in the splenic vein or a mesenteric vein (Fig. 36-6), and the resting portal venous pressure is measured with a water manometer (N = 6 to 13 cm  $H_2O$ ). Portal pressure is measured as soon as possible in the procedure because prolonged anesthesia may complicate its interpretation. An injection of iodine-based contrast medium at a dose of 0.5 to 1 ml/kg is then quickly made. Lateral and possibly ventrodorsal and oblique radiographs are made at the end of the injection. Contrast medium given to a normal cat or dog should flow into the portal vein, enter the liver, and branch multiple times, opacifying the extrahepatic and intrahepatic portal vasculature. Diversion of the contrast medium into the systemic circulation indicates PSS (Fig. 36-7). Measurement of portal pressure and a liver biopsy can be performed during the operative techniques; they are required to distinguish acquired PSS from congenital PSS, which is essential to rendering an accurate prognosis and developing the correct treatment plan. As a general rule, cases of congenital PSS are usually single whereas acquired PSS are multiple, so the mesenteric portography may suggest a diagnosis. It may be necessary to repeat the contrast study after congenital PSS ligation if there is concern about the adequacy of the intrahepatic portal vasculature. In addition, it has been shown that the degree of intrahepatic portal vessel opacification on post-ligation portography is predictive for outcome (Lee et al., 2006).

#### **ULTRASONOGRAPHY**

Abdominal ultrasonagraphy (US) is the preferred diagnostic modality for evaluating the hepatobiliary system in dogs and cats. Operating on the principle that a pulse of sound (echo) can be reflected when it passes through the interface between two different materials, US can detect differences between homogeneous liquids of low echogenicity, such as blood and bile, and more heterogeneous echogenic structures made up of several soft tissues. Whereas abdominal effusion obscures abdominal detail on survey radiography, it enhances the ability of US to detect abnormalities (Fig. 36-8). However, bone and gas-filled organs reflect the sound beam completely (acoustic shadowing) so that structures beneath cannot be imaged by US. The procedure does not require anesthesia, but the patient must be still, and good contact between the transducer and abdominal skin must be ensured by clipping the hair coat and applying acoustic coupling gel. Animals are usually positioned in dorsal or lateral recumbency. The hepatic parenchyma, gallbladder, large hepatic and portal veins, and adjacent caudal vena cava are all visible in the liver of the normal cat and dog. Unlike plain radiography, which requires two views to complete the study, US

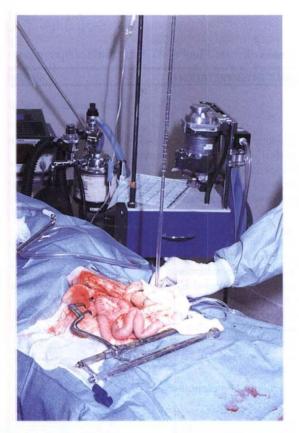

FIG 36-6

makes many slices through several planes to create a threedimensional reconstruction of the target structures.

Performing US and interpreting the recorded images are a blend of technical skill and experience. It is also important to remember that US is very sensitive to the presence of lesions but does not diagnose what the lesions are (i.e., it cannot yield a histological diagnosis). With a few exceptions, which predominantly involve lesions of the biliary tract and vessels, the ultrasonographic appearance of a variety of both benign and malignant hepatic lesions can appear very similar and histology of a liver biopsy is usually required for diagnosis. An animal should never be euthanized on the basis of an ultrasonographically identified "tumor" without histological confirmation because benign nodular hyperplasia or focal inflammatory lesions can look the same. Table 36-3 outlines the typical appearances of different hepatic lesions on ultrasonography.

Neoplasia may appear as hyperechoic or hypoechoic and focal or diffuse. Hepatic lymphoma often appears diffusely hypoechoic but can also appear hyperechoic. Some tumors, such as metastatic hemangiosarcomas, have a classically nodular hypoechoic appearance (Fig. 36-9).

FINDING	POSSIBLE INTERPRETATIONS
Parenchyma Anechogenicity	
Focal	Cyst(s)—may be singular or multiple with septae; thin-walled Abscess(es)—may be poorly demarcated and have a heterogeneous echo pattern Hematoma(s)—appearance depends on maturity Lymphoma—may look like cyst if solitary
Hypoechogenicity	
Focal	Focal or multifocal neoplasia Regenerative nodule formation Extramedullary hematopoiesis Normal liver surrounded by hyperechoic liver Hematoma(s)
Diffuse	Abscess(es) or granuloma(s) Neoplastic or inflammatory cell infiltrates Passive congestion Hepatocellular necrosis Amyloid Extramedullary hematopoiesis
Hyperechogenicity	
Focal  Diffuse	Focal or multifocal neoplasia Nodular hyperplasia Mineralization (creates shadowing artifact) Fibrosis Gas (creates reverberation artifact) Hematoma or abscess Fatty infiltration (attenuates the sound beam) Lymphoma
	Fibrosis Neoplastic or inflammatory cell infiltrates Steroid hepatopathy (dogs only)
Tubular Structures—Biliary Tract	
Distended gallbladder Distended gallbladder and cystic duct Distended gallbladder and common bile duct Focal areas of gravity-dependent hyperechogenicity within biliary tract or gallbladder that cause acoustic shadowing Focal areas of hyperechogenicity within gallbladder that settle to dependent portion of gallbladder when animal's	Extrahepatic bile duct obstruction; persistent or recently relieved Severe cholangitis complex (cats) Choledochal cyst (rare) Normal (prolonged fasting) Cystic duct obstruction Extrahepatic bile duct obstruction; persistent or recently relieved Cholelithiasis "Sludged" or inspissated bile from severe cholestasis, prolonged anorexia, and dehydration
position changes Stellate or "kiwi fruit" appearance to gallbladder Intraluminal echoic masses in gallbladder Apparent thickened gallbladder wall	Gallbladder mucocele Neoplasia (polyp, malignant neoplasm) Adherent inspissated bile Cystic hyperplasia (focal) Cholecystitis, cholangitis Infectious canine hepatitis Hypoalbuminemia with edema formation Abdominal effusion Neoplasia

FINDING

**TABLE 36-3** 

Ultrasonographic Findings in Dogs and Cats with Hepatobiliary Diseases—cont'd

#### Tubular Structures - Blood Vessels

Dilated hepatic veins and portal veins

Prominent hepatic arteries

Distended portal vein with reduced velocity and flow Inapparent hepatic vessels

Inapparent portal veins

Aberrant vessel that communicates with systemic circulation Connection between a portal vein and an artery within one or more liver lobes

Many tortuous veins clustered around left kidney and along colon

#### **POSSIBLE INTERPRETATIONS**

Right-sided congestive heart failure

Pericardial disease

Intrathoracic caudal vena cava occlusion Hepatic vein occlusion (Budd-Chiari syndrome)

Reduced portal blood flow

Portal hypertension of any cause (by Doppler)

Cirrhosis

Severe fatty infiltration

Congenital portosystemic shunt

Portal vein thrombus

Intrahepatic portal vein hypoplasia

Intrahepatic or extrahepatic congenital portosystemic shunt

Arterioportal venous fistula

Acquired portosystemic shunts associated with portal hypertension

FIG 36-9

Ultrasonographic appearance of a hepatic hemangiosarcoma in a dog. Note the multiple hypoechoic nodules. (Image courtesy the diagnostic imaging department, The Queen's Veterinary School Hospital, University of Cambridge.)

Contrast-enhanced ultrasonography has recently been used to improve visualization of small hepatic metastases in dogs (O'Brien 2007). Typically, hepatic lipidosis in cats causes an increase in echogenicity and so does diffuse fibrosis such as cirrhosis in dogs. However, a cirrhotic liver may appear normal ultrasonographically.

Dilated anechoic (black) vascular channels and echoic bile ducts can be identified; biliary tract imaging is particularly useful in cats with suspected biliary tract disease (Fig. 36-10) or dogs and cats with suspected EBDO. The bile duct

FIG 36-10

can be followed ultrasonographically along its course toward the small intestine, and lesions in the pancreas or duodenum obstructing it can be identified.

A dilated gallbladder may indicate prolonged anorexia, unless dilated bile ducts, particularly the common bile duct, are also seen, which supports EBDO or chronic cholangitis/ cholangiohepatitis in cats (see Fig. 36-10). Intrahepatic or extrahepatic anomalous vessels may also be identified in animals with clinicopathologic evidence of severe chronic hepatobiliary disease or congenital PSS (Fig. 36-11). Congenital PSSs are typically single vessels, whereas acquired

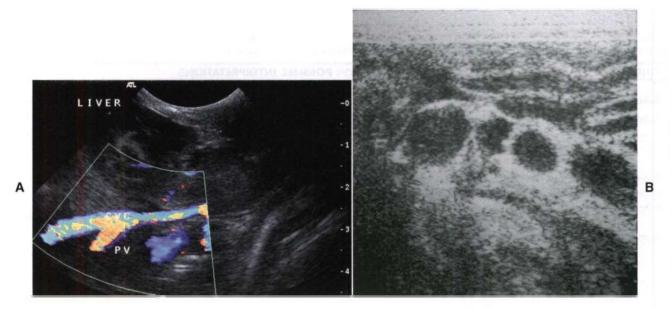

FIG 36-11

**A,** Doppler ultrasonographic findings of a congenital extrahepatic portocaval shunt in a young English Springer spaniel. **B,** Ultrasonographic appearance of multiple extrahepatic acquired portosystemic shunts in a 6-year-old German Shepherd Dog with noncirrhotic portal hypertension. *CVC*, Caudal vena cava; *PV*, portal vein. (Images courtesy the diagnostic imaging department, The Queen's Veterinary School Hospital, University of Cambridge.)

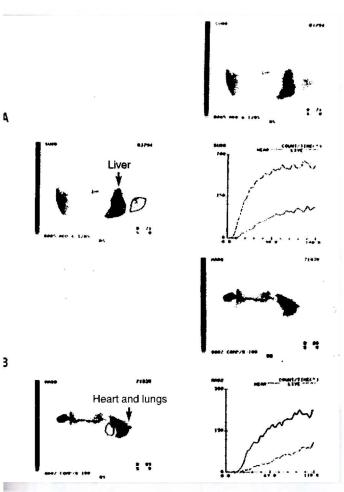

PSSs are usually multiple. Use of Doppler color-flow imaging confirms the location of the suspicious vessel(s) and the direction of blood flow within it. Doppler imaging can also provide supportive evidence of intrahepatic portal hypertension by allowing the assessment of the speed and direction of portal flow. Portal blood flow toward the liver (hepatopetal) is normal; away from the liver (hepatofugal) is abnormal. Whether the lesion is determined to be focal or diffuse, US can also be used as a guide to obtain diagnostic specimens for cytologic or histopathologic evaluation. US has developed into a valuable and critically important adjunct to diagnosis of hepatobiliary disease of cats and dogs by allowing characterization of structural changes not possible by any other modality and by providing a way to obtain needle liver biopsy specimens and bile duct samples in a visualized manner without the need for general anesthesia.

#### **SCINTIGRAPHY**

Other imaging modalities, such as scintigraphy (nuclear imaging), magnetic resonance imaging, contrast-enhanced harmonic ultrasound, and computed tomography, are available primarily through teaching or larger referral institutions. Of these imaging modalities, scintigraphy has been evaluated most thoroughly for diagnosis of hepatobiliary disease in cats and dogs. The isotope selected most often for clinical use is technetium-99m (99mTc), which is incorporated into the radiopharmaceutical specific for the planned study. For example, 99mTc bound to sulfur colloid, which is phagocytized by monocyte-macrophage cells of the liver and spleen, is given to assess liver mass. Images are made by col-

lection of emissions from decaying isotope using a gamma camera focused over the animal's liver region and recorded on radiographic film. The isotope has a short (6-hour) half-life; thus, although the animal must be relatively isolated for 24 to 48 hours and urinary and fecal waste stored until radioactivity has fallen to background levels, there is minimal radiation hazard to the animal or involved personnel. To distinguish medical from surgical causes of jaundice, <sup>99m</sup>Tc is combined with disofenin (Hepatolite). After an intravenous injection of radiopharmaceutical, scintigraphic images are made sequentially over 3 hours to determine whether the isotope has been taken up by the liver, excreted into the biliary tract, and expelled into the intestine. In cats and dogs with EBDO, no evidence of radiopharmaceutical is detected in the gallbladder or intestine.

Another application of scintigraphy is used in the diagnosis of PSS in cats and dogs. Following placement of pertechnetate labeled with <sup>99m</sup>Tc into the descending colon, the vascular path taken by the isotope after absorption is plotted. Time/activity curves determine whether the isotope arrived in the liver first, which is normal, or in the heart and lungs, which is compatible with any kind of portal venous bypass of the liver (Fig. 36-12). This approach has the advantage of specifically evaluating the portal blood supply rather than the hepatic mass, which may or may not be reduced in animals with congenital PSS or primary hepatobiliary disease and acquired PSS. The test results do not provide anatomic detail but only evidence of the presence or absence of congenital *or* acquired portosystemic shunting. Transcolonic portal scintigraphy is most helpful in confirming the

#### FIG 36-12

presence of a congenital PSS in a cat or dog with atypical clinicopathologic test results, equivocal abdominal ultrasound findings (e.g., normal-size liver, no identifiable vessel arising from the portal vein), and no evidence of portal hypertension (e.g., ascites).

#### LIVER BIOPSY

#### **General Considerations**

For many primary hepatobiliary diseases of cats and dogs, a hepatic biopsy is needed to establish a final diagnosis and prognosis. In some cases bile culture is also imperative. Biopsy is indicated to (1) explain abnormal results of hepatic status and/or function tests, especially if they persist for longer than 1 month; (2) explain hepatomegaly of unknown

#### BOX 36-2

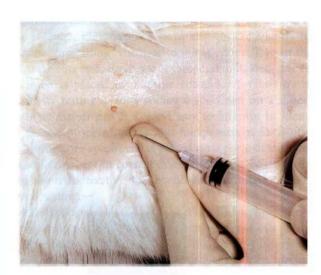

#### Patient and Operator Considerations for Hepatic Biopsy

#### **Patient**

- Characteristics of the suspected hepatobiliary disorder: liver size (small, normal, enlarged); texture (fibrotic or friable); focal, multifocal, or diffuse distribution; presence of abdominal effusion
- 2. Clinical stability and suitability for anesthesia
- 3. Coagulation status and platelet count

#### Operator

- 1. Available equipment
- 2. Experience with chosen technique
- 3. Complication rate for chosen technique
- 4. Size of specimen needed
- 5. Access to reliable veterinary pathology laboratory

#### FIG 36-13

A 4-year-old spayed female domestic short-haired cat with suspected hepatic lipidosis positioned in right lateral recumbency for blind fine-needle aspirate for cytology. With care taken to avoid the spleen, the needle is directed craniomedially into the liver.

cause; (3) determine hepatic involvement in systemic illness (although biopsy is not always necessary for this); (4) stage neoplastic disease; (5) objectively assess response to therapy; or (6) evaluate progress of previously diagnosed, not specifically treatable disease. Percutaneous hepatic biopsy is *not* performed if there is a good chance that the disease can be corrected surgically, such as in some cases of EBDO or congenital PSS; instead, a specimen is obtained at the time of surgery to complete the diagnostic evaluation. Several approaches are available; choice is dictated by patient and operator considerations (Box 36-2). In addition, in most cases of hepatic disease the accuracy of histological diagno-

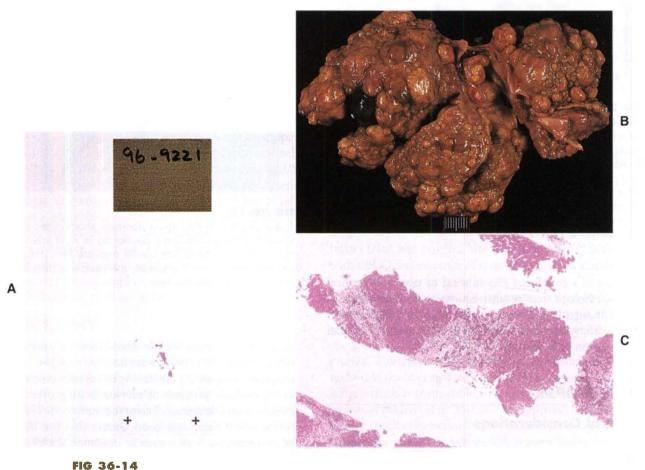

sis is better with larger (i.e., surgical or laparoscopic) rather than smaller (i.e., needle) biopsies.

All cats and dogs undergoing hepatic biopsy are fasted for at least 12 hours, regardless of the approach selected. In general, percutaneous needle core biopsy or aspiration (for cytologic analysis) of a single cavitary or solid lesion highly likely to be nonlymphoid cancer should be avoided unless the owner is unwilling to permit surgery for complete resection. Fine-needle aspiration of the liver for cytologic analysis is rarely advisable because of low diagnostic yield and often misleading results. The exceptions to this are for quick diagnosis of hepatic lipidosis in cats and possibly for suspected hepatic lymphoma, although even then the diagnosis may need to be confirmed histologically (Fig. 36-13). However, an overall correlation of only 30% in dog and 51% in cats was found in one study comparing the cytologic diagnosis with the histopathologic diagnosis of a variety of liver diseases (Wang et al., 2004).

In an especially small and/or firm fibrotic liver, it is difficult to obtain a biopsy specimen by percutaneous needle methods; small, fragmented specimens that are challenging

to interpret are often the result (Fig. 36-14). There is less than a 40% correlation between 18-gauge needle biopsy and wedge biopsy for certain hepatobiliary diseases (i.e., chronic hepatitis/cirrhosis, cholangitis, portovascular anomaly, fibrosis). If a needle technique is selected, the largest available instrument is used (preferably 14 gauge; minimum 16 gauge) and multiple samples are taken to ensure samples adequate for examination.

The animal's coagulation status is determined before a liver biopsy is performed, regardless of the approach. Ideally, a complete coagulation profile (one-stage prothrombin time [OSPT], APTT, fibrin degradation products, fibrinogen content, platelet count) is obtained; a platelet count and an activated clotting time or whole blood clotting time in a glass tube, as a screening test of the intrinsic coagulation cascade, are also acceptable. Bleeding after ultrasound-guided biopsy is more likely if the platelet count is less than 80,000 cells/µl or if the OSPT (dogs) or APTT (cats) is prolonged (Bigge et al., 2001). If possible, von Willebrand's factor is measured in susceptible breeds in advance of biopsy because results of standard coagulation tests are usually normal in affected

**A,** Liver specimen obtained percutaneously (with ultrasound guidance) from a dog with hepatic fibrosis and nodular regeneration (**B**). The specimen was difficult to obtain because the liver was firm and rubbery in texture. **C,** The resultant sample was difficult to interpret histologically.

dogs. A buccal mucosa bleeding time test provides indirect assessment of platelet function (see Chapter 87). In dogs with von Willebrand's disease, desmopressin acetate (DDAVP) is given (1  $\mu$ g/kg intranasal preparation subcutaneously) before surgery to enhance shift of von Willebrand's factor activity from endothelial cells to the plasma.

Mild abnormalities in coagulation test results do not preclude liver biopsy. In fact, results of routine coagulation tests may not correlate with liver bleeding times, as was found in one study of human patients. Liver biopsy should be delayed if there is clinical evidence of bleeding or marked abnormalities in results of coagulation tests. Because animals with complete EBDO may be vitamin K deficient (manifested by prolongation of both OSPT and APTT), treatment with vitamin K<sub>1</sub> (0.5 to 1.0 mg/kg [maximum of 10 mg] subcutaneously q12h for 3 treatments) is indicated for 1 or 2 days before surgery. Vitamin K supplementation can also improve coagulation times in animals with other liver disease, particularly cats. Repeating the OSPT and APTT within 24 hours after administration of vitamin K1 should demonstrate normal or near-normal values. If not, the dose can be adjusted and the procedure delayed. Although it may not seem rational to give vitamin K1 to animals with severe parenchymal hepatic disease before surgery, it has been of benefit to some animals and, if given properly, can do no harm. These animals may have high serum activity of proteins induced by vitamin K antagonism (PIVKA) that could impart bleeding tendencies. If there has been minimal improvement in coagulation test results after vitamin K1 has been administered, fresh frozen plasma is administered before biopsy. If bleeding is excessive during or after biopsy and cannot be controlled locally with direct pressure or application of clot-promoting substances, fresh whole blood or plasma is given (see Chapter 83 for transfusion guidelines).

## Techniques

Information gathered before biopsy must support the fact that the likelihood of acquiring a diagnostic sample without complications is high. A specimen procured from any area of the liver is considered representative of the disease. Because only a small stab incision large enough to accommodate the biopsy needle is needed (a No. 11 blade is the perfect choice for this purpose), healing in hypoalbuminemic animals is not compromised. If the operator is confident with the biopsy procedure, there is little time involved and only heavy sedation is required. If the results are nondiagnostic, a larger specimen is obtained for histopathologic examination, usually by laparoscopy or laparotomy.

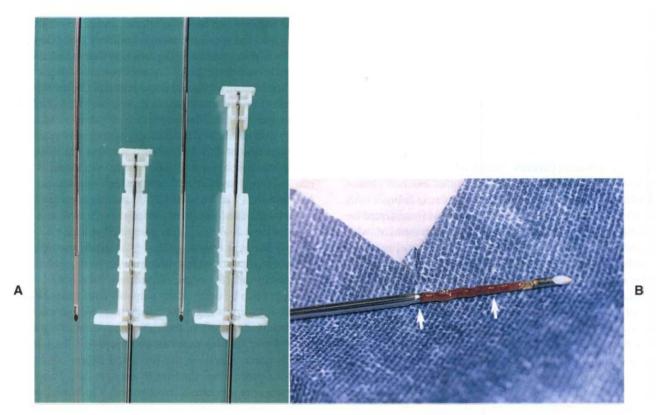

Biopsy can be performed blindly if the cat or dog has generalized hepatomegaly and the operator is confident of the path of the needle. The most common needle biopsy instruments are the Tru-Cut (Cardinal Health) and Jamshidi Menghini (Cardinal Health; Kormed Inc.) needles. The Jamshidi Menghini biopsy needles can be operated with one hand, and aspiration is used to sever and contain the specimen within the barrel of a 6- or 12-ml syringe. The Tru-Cut

needle requires two hands to operate and relies on the tissue falling into the specimen trough and then being severed by the sharp outer cannula (Fig. 36-15). One-handed operatable semi-automatic (e.g., Tenmo Evolution biopsy needle, Cardinal Health; VET-core biopsy needle, Global Veterinary Products Inc) and automatic (e.g., Pro-Mag Ultra Automatic biopsy instrument, Manan Medical Products; Bard Biopty biopsy instrument and Bard Biopty-Cut biopsy needle, Bard Inc) versions of this instrument are also available. These biopsy needles are intended for single use. Either the automatic biopsy instrument or the semi-automatic biopsy needle device can be used to obtain liver biopsies in dogs, but only the semi-automatic biopsy needle device should be used in cats. A recent study identified a high risk of fatal complications (i.e., unexpected fatal shock reaction) when an automatic biopsy instrument was used to obtain liver biopsies in cats (Proot and Rothuizen, 2006).

Biopsy can be done of any palpably enlarged lobe as long as care is taken to angle the needle to avoid puncturing the gallbladder. Most often, the animal is placed in right lateral recumbency for this purpose and biopsy of the left lateral lobe is done. Elevating the head and thorax slightly may assist in "presenting" the liver to the operator. Two or three complete core specimens are obtained; if indicated, one core specimen is placed in a sterile container for culture and sensitivity testing. Gently rolling a specimen on a slide for cytologic assessment is a good way to attempt to identify the disease process quickly and inexpensively. Each of the remaining core specimens is placed on a piece of stiff paper (e.g., filter paper) in correct orientation (Fig. 36-16) before immersion in fixative for histologic examination and/or special testing.

After biopsy, a small bandage is applied to keep the site clean during recovery, and the animal is placed in a position to allow body weight to compress the region of the biopsy sites in the liver (e.g., left lateral recumbency). Consideration should be given to postoperative analgesia; puncture of the liver capsule can be painful. The animal should be monitored carefully for any evidence of hemorrhage for several hours after the procedure. As long as the biopsy procedure proceeded smoothly and without unpleasant surprises (animal awake and struggling), only basic monitoring of mucous membrane color and the skin puncture site is needed. Naturally, if excessive hemorrhage or damage to other organs occurs with this blind technique, detection and treatment may be delayed.

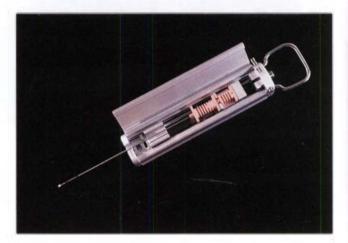

Visualized percutaneous needle biopsy, with the aid of either US (Fig. 36-17) or modified laparoscopic equipment (Fig. 36-18), allows selection of the site(s) and direct or indirect inspection after the biopsy. When the procedure is properly performed, serious complications are few. In an animal in which diffuse or multifocal hepatobiliary disease is suspected, multiple biopsy specimens are obtained safely. General anesthesia is usually required for use of a modified laparoscope. Aspiration of the gallbladder for cytologic analysis and culture can be accomplished with US guidance or by laparoscopy. Bile leakage may occur, even if a small-gauge

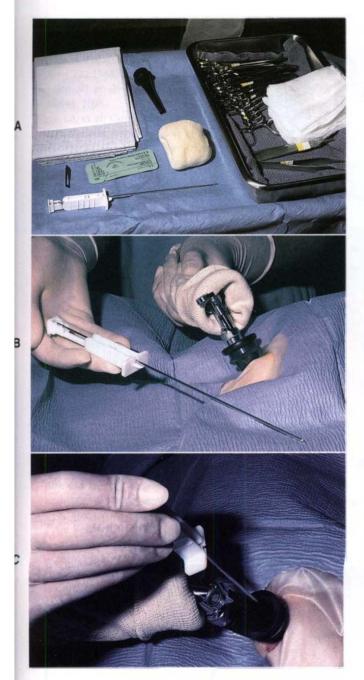

FIG 36-18
Modified laparoscopic approach for liver biopsy.

A, Readily available materials needed for the procedure.

B, A Tru-Cut biopsy needle is used for obtaining liver specimens. C, The liver is first inspected, and then the needle is passed through a sterile otoscope cone into the liver for tissue sampling. See Bunch et al. (1985) in Suggested Readings for further details on this procedure.

needle is used, so attempts are made to completely evacuate the gallbladder, and the needle should be placed in the gallbladder through the liver parenchyma to help prevent leakage. Some surgeons prefer to obtain bile during laparotomy when a purse-string suture can be applied to the aspiration site to prevent seepage. Large-volume abdominal effusion hinders direct inspection of the liver and associated structures and must be removed before laparoscopic biopsy is attempted.

An operative approach (laparoscopy [Fig. 36-19], laparotomy) is preferred for liver biopsy if the liver is small, US equipment is not available, or the operator is not experienced with the aforementioned percutaneous needle methods. Laparotomy is perfectly acceptable for dogs and cats that are good anesthetic risks and allows thorough examination of the liver, biliary tract, and portal vein as well as other abdominal structures, such as lymph nodes. Bile can be acquired easily and safely. The procedure is more prolonged, and healing complications may arise in severely hypoalbuminemic animals, notably those with intractable ascites, but larger samples for histopathologic examination and special staining techniques are obtainable (Fig. 36-20) and hemorrhage can be arrested directly. Use of nonabsorbable suture material and small cranial or flank incisions may lessen incision complications. Obviously, this is the approach of choice for surgically correctable diseases; a liver biopsy specimen is obtained concurrently.

As for the percutaneous biopsy techniques, liver and/or bile specimens for microbiologic culture are aseptically processed first. Impression smears for cytologic analysis are then made by gently touching the specimen to a slide before placing it in fixative. Excess blood is removed by blotting the sample on gauze before slides are made. Abnormal populations of cells (e.g., mast cells, lymphoblasts) are readily detectable using rapid stain systems such as Diff Quik (Harleco, Gibbstown, N.J.). For routine processing and histopathologic examination, liver tissue specimens are submerged in buffered 10% formalin at a ratio of at least 10 parts formalin to 1 part tissue. Samples for copper histochemical staining or tissue quantification are harvested and fixed or preserved according to the specifications of the pathology laboratory selected to do the assays. Other special stains for infectious agents or fibrous tissue, amyloid, glycogen, and other metabolic products are available, and their use is discussed with the attending pathologist before the tissue specimen is obtained. A portion of the specimen can be frozen for molecular studies (e.g., PCR for organisms or tumor clonality).

SYSTEMIC DISEASE

## **GENERAL CONSIDERATIONS**

The causes, clinical signs, and prognosis of hepatobiliary tract diseases in cats are very different from those of dogs. Causes of liver disease in cats, both primary and secondary, are outlined in Table 37-1. Cats typically have hepatobiliary disease or acute hepatic lipidosis, but chronic parenchymal disease is uncommon in this species; in addition, feline liver disease rarely progresses to cirrhosis, as is sometimes the case in dogs. The clinical signs of hepatobiliary disease in cats are generally nonspecific and similar to the signs of inflammatory bowel disease (IBD) and pancreatitis; the three conditions may co-exist, further confusing diagnosis. Hepatic lipidosis presents with more classical signs of liver disease, including jaundice and encephalopathy. The important differences between feline and canine hepatobiliary diseases are outlined in Table 37-2 and Fig. 37-1.

The feline hepatopathies in this chapter are described approximately in order of their frequency in clinical practice in the United States. Historically, hepatic lipidosis has been most common in the United States and cholangitis most common in Europe, but lipidosis is becoming increasingly common in Europe, and cholangitis is now commonly recognized in the United States.

## HEPATIC LIPIDOSIS

## **Etiology and Pathogenesis**

Feline hepatic lipidosis may be primary or secondary to another disease, but in either case it is associated with a high mortality, unless the cat is intensively fed.

#### PRIMARY HEPATIC LIPIDOSIS

Primary or idiopathic hepatic lipidosis usually affects obese cats and remains the most common hepatic disease of cats in North America; it is also now emerging as an increasingly common problem in Europe. It is effectively an acute hepatopathy with a massive accumulation of fat in hepatocytes leading to acute loss of hepatocyte function, which is reversible if the fat can be mobilized (Fig. 37-2). The reason for the differences in prevalence in different countries is unknown but intriguing. Some researchers suggest environmental differences (e.g., differences in outdoor/indoor lifestyle or feeding habits), genetic differences among cats, or both.

The pathogenesis of primary hepatic lipidosis remains incompletely understood, but it seems to involve a combination of excessive peripheral lipid mobilization to the liver, deficiency of dietary proteins and other nutrients that would usually allow fat metabolism and transport out of the liver, and concurrent primary disturbances in appetite. Excessive mobilization of peripheral fat occurs particularly during periods of anorexia or stress in previously overweight cats. Concurrently, anorexia results in deficiencies of dietary proteins and other nutrients; cats are particularly susceptible to these because of their high dietary requirements (see Table 37-2). Some of these nutrients are important in fat metabolism and mobilization, particularly methionine, carnitine, and taurine, so deficiencies in these nutrients are implicated as contributing to the pathogenesis of the disease.

TABLE 37-1

## Clinically Relevant Hepatobiliary Diseases in Cats

PRIMARY	SECONDARY
Common	
Idiopathic lipidosis Neutrophilic cholangitis Lymphocytic cholangitis	Secondary lipidosis Hyperthyroidism Pancreatitis Diabetes mellitus
Uncommon or Rare	
Congenital portosystemic shunt Extrahepatic bile duct obstruction Liver flukes (except in hunting cats in endemic areas) Primary neoplasia Infections (see Box 37-5) Drug- or toxin-induced hepatopathy Biliary cysts Sclerosing cholangitis/biliary sclerosis Hepatic amyloidosis Intrahepatic arteriovenous fistula	Secondary neoplasia (less common than primary) Biliary stasis associated with extrahepatic sepsis Hepatic abscess

Methionine is an important precursor in the synthesis of an important hepatic antioxidant, glutathione, and hepatic concentrations of glutathione may decrease markedly in cats with hepatic lipidosis. Relative arginine deficiency will contribute to the resultant hepatic encephalopathy caused by decreased urea cycle activity. Concurrent primary appetite disturbances result in persistent and marked anorexia, which is likely due to disturbances in the complex neurohormonal control of appetite. Recent studies have suggested peripheral insulin resistance does not play a significant role in the disease.

### SECONDARY HEPATIC LIPIDOSIS

Secondary hepatic lipidosis is also common in cats; its pathogenesis is similar to the primary disease but complicated by the more marked neuroendocrine responses to stress. Secondary lipidosis can therefore be seen in cats that are less obese than those presenting with the primary disease and even in cats with normal or thin body condition. Any anorexic cat with concurrent disease must therefore be regarded as at high risk of hepatic lipidosis, and appropriate feeding support should be instituted as rapidly as possible. Secondary lipidosis may occur in association with any disease causing anorexia in cats but has been most commonly recognized in cats with pancreatitis, diabetes mellitus (DM), other hepatic disorders, IBD, and neoplasia.

#### **Clinical Features**

Most affected cats are middle-aged, but they can be of any age or sex. There is no reported breed predilection. Cats with

primary lipidosis are commonly obese, are housed indoors, and have experienced a stressful event (e.g., introduction of a new pet into the household, abrupt dietary change) or an illness that causes them to become anorexic and lose weight rapidly. The initiating event is not always known. Secondary lipidosis may affect cats of normal or thin body condition as well as obese animals, and the clinical signs are complicated by the signs of the concurrent disease. For example, the clinical signs of acute diabetic ketoacidosis are similar to those of developing hepatic lipidosis.

Clinical signs are typical of an acute (reversible) loss of hepatocyte function and of hepatocyte swelling with resultant intrahepatic cholestasis. Cats are usually jaundiced, and have intermittent vomiting and dehydration. They may also have diarrhea or constipation. There is usually palpable hepatomegally on physical examination. Hepatic encephalopathy, most often manifested as depression and ptyalism, is related to severe hepatocellular dysfunction and relative arginine deficiency, to which the anorexic cat is predisposed. Previously obese cats have extensive loss of muscle mass but maintain certain fat stores, such as those in the falciform ligament and inguinal region (Fig. 37-3).

## **Diagnosis**

The only truly definitive and reliable method of diagnosis and of identifying concurrent and causative conditions is histopathology of a wedge biopsy of liver obtained at laparotomy or laparoscopy or (less reliably) a Tru-Cut biopsy taken under ultrasound guidance. However, all of these procedures require a general anesthetic, and the majority of cats with hepatic lipidosis are too ill on presentation to be safely anesthetized. Therefore cytology of a fine needle aspirate (FNA) of the liver obtained either blindly or under ultrasonographic guidance in an awake or sedated cat can give a preliminary diagnosis; this will allow intensive management and tube feeding for a few days to stabilize the patient before anesthesia is considered for a more definitive diagnosis. Because coagulopathies are common in cats with lipidosis, a few days of therapy will help correct them before considering surgery. The clinician must be aware, however, that FNA cytology, although useful for emergency diagnosis and management, can be misleading in cats, and hepatic parenchymal disease can be misdiagnosed as lipidosis using this technique. In addition, concurrent diseases of the liver and other organs (including the pancreas and small intestine) will be overlooked without a laparoscopic or surgical biopsy. It is important to differentiate mild to moderate lipid accumulation in hepatocytes, which is common in sick and anorexic cats and causes no clinical problems, from clinically severe lipidosis on cytology (see Fig. 37-2).

FNAs can be taken under ultrasonographic guidance while the cat is being imaged or be obtained blindly if there is palpable hepatomegaly. The procedure is performed in a similar way to aspiration of a mass: The enlarged liver is palpated, and the abdominal wall overlying it is clipped and prepped. A 22-gauge needle is passed through the skin into the liver from ventrally on the left side, which prevents inadvertent puncturing of the gallbladder, and gentle suction is applied to a 5-ml syringe two or three times, before withdrawing and gently expressing the needle contents onto a slide (see Fig. 36-13). Analgesia is recommended for either procedure because puncture of the liver capsule is painful. Opiate partial agonists, such as buprenorphine, are a good choice; buprenorphine appears to be more effective than butorphanol as an analgesic in cats.

Clinically relevant hepatic lipidosis is usually easily recognizable on routine Giemsa or Diff-Quik staining of cytology samples or routine hematoxylin and eosin-stained histology samples (see Fig. 37-2). It is possible to use special staining procedures with Oil red O applied to snap-frozen biopsy samples to confirm that hepatocellular vacuolation is indeed lipid, but these procedures are not practical in a private practice setting. In addition, glycogen accumulation is uncommon in feline (as opposed to canine) hepatocytes.

Clinicopathologic findings reflect cholestasis and marked hepatocellular dysfunction. Hyperbilirubinemia is present in more than 95% of cases, and the activities of the hepatocellular enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are also markedly elevated in most cats. Alkaline phosphatase activity (ALP) is also markedly

elevated in more than 80% of cases; this is particularly relevant in cats, in which this enzyme has a short half-life and no steroid induction (see Table 37-2). In cats with classical primary (idiopathic) lipidosis, a particular hallmark of the disease is an inappropriately low γ-glutamyl transferase (GGT) activity, which is only mildly increased in the face of marked increase in the activity/concentration of the other cholestatic markers (i.e., bilirubin and ALP). This is in contrast to cats with primary biliary tract disease in which both GGT and ALP activities are high. However, in cats with secondary lipidosis associated with an underlying primary hepatopathy or pancreatic disease, GGT activity may be high as well. Therefore finding a high GGT activity does not rule out hepatic lipidosis but should stimulate a search for an underlying cause. Blood urea (BUN) concentration is low in more than half of the cats with lipidosis, reflecting generalized hepatocyte dysfunction. Electrolyte abnormalities are relatively common and can contribute to mortality if not addressed. Up to a third of cats are hypokalemic, and hypophosphatemia has been reported in 17% of the cases; hypomagnesemia has also been reported in cats with lipidosis. Hypokalemia was a poor prognostic indicator in one study (Center et al., 1993). There is no value in measuring serum bile acids as an indication of hepatic function in these cats because they will be high as a result of the concurrent cholestasis. Fasting cholesterol and glucose concentrations may also be high, and sometimes hyperglycemia is so marked as to result in glucosuria. This is usually a stress/metabolic response and typically resolves after appropriate therapy. However, some cats may become diabetic as a result of an underlying disease process, or DM may be the cause of their lipidosis; therefore blood and urine glucose and ketones should be monitored carefully. The appearance of ketonuria in addition to glycosuria in a hyperglycemic cat is highly suggestive of overt DM.

Hemostatic abnormalities are common in cats with lipidosis, occurring in between 20% and 60% of the cases. They are more reliably detected with the PIVKA test (proteins invoked by vitamin K absence; Center et al., 2000), but PIVKA tests are not readily available to many practitioners, and overt prolongation of clotting times are also seen in some cases. Anemia is present in about a quarter of cats, and there is often an increase in Heinz bodies. Because lipidosis is non-inflammatory, a neutrophilia is not characteristic but may occur as a result of another underlying disease.

Radiographs show hepatomegaly in most cases, whereas abdominal effusion is uncommon (Fig. 37-3). Ultrasonography helps differentiate parenchymal from biliary tract disease and also allows assessment of other abdominal organs to look for underlying disease, particularly of the pancreas and intestine. Characteristically, the lipidotic liver appears hyperechoic, although this is not a specific finding and can also be seen in cats with other generalized parenchymal diseases, such as lymphoma or hepatic amyloidosis.

Additional diagnostic tests are performed to determine the presence of concurrent illnesses that could be causing protracted anorexia and secondary hepatic lipidosis. Tests

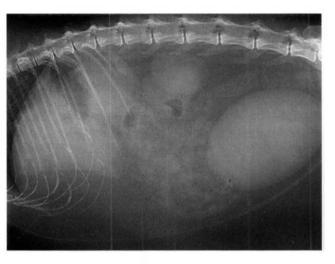

FIG 37-3
Lateral abdominal radiograph of a Domestic Short-haired cat with hepatic lipidosis secondary to prolonged fasting because of a diet change. are selected according to clues in the history, physical examination, and clinicopathologic and ultrasonographic evaluations. For example, serum feline specific pancreatic lipase immunoreactivity should be evaluated in cats suspected of having pancreatitis (see Chapter 40).

### **Treatment and Prognosis**

Treatment recommendations for cats with hepatic lipidosis are outlined in Box 37-1. The single most important factor in reducing mortality is early and intensive feeding of a highprotein diet. In most cases, this requires some form of tube feeding. If the cat is very ill at presentation, a nasoesophageal tube can be placed for the first few days while the cat is stabilized (Box 37-2 and Fig. 37-4) and then an esophagostomy or gastrostomy tube may be placed for long-term feeding (see Box 37-2 and Fig. 37-5). Most cats need 4 to 6 weeks of tube feeding, but many cats can be sent home with a gastrostomy tube in place for home feeding once they have stabilized. A high-protein diet, such as those manufactured for feline intensive care patients, is ideal (e.g., Royal Canin feline concentration instant or Hills AD diet or "Fortol" liquid feed [Arnolds]). In some cats, however, a high-protein diet will worsen signs of encephalopathy during the first few days of therapy. Attempts should be made to control this by other methods, such as by feeding smaller amounts more frequently rather than by reducing the protein content of the diet. Concurrent pancreatitis does not alter the dietary recommendations; the current recommendations in cats with pancreatitis is to feed them as soon as possible and not to restrict fat (see Chapter 40).

Fluid and electrolyte abnormalities should also be addressed effectively in the first few days, and antiemetics

## BOX 37-1

#### Outline of Treatment of Hepatic Lipidosis in Cats

- Treat any identifiable underlying cause as effectively as possible, but also concurrently start other treatment: Do not rely on treating the cause alone to resolve the disease in secondary cases; in most cases the anorexia will persist unless active measures are taken to feed the cat.
- Institute fluid therapy and nutritional support as soon as possible.
  - Fluid therapy: Intravenous fluid support is necessary in the early stages of therapy (maintenance rates + replacement for any fluid lost, e.g., in vomiting). Measure and replace any electrolyte deficits, particularly potassium and phosphate. Carefully monitor blood glucose and electrolytes, particularly potassium and phosphate, which may become low during treatment. Normal saline with added potassium chloride as necessary is the most useful fluid. Dextrose is avoided because it may worsen hyperalycaemia and lactated Ringer's may be contraindicated with marked hepatocellular dysfunction because the lactate may not be metabolized to bicarbonate. There is NO evidence that adding insulin to the fluids helps; in fact, it increases the risk of serious hypokalaemia and hypophosphatemia. After the first few days, fluid and electrolyte needs can be supplied via the feeding tube.
  - Nutritional support should be instituted as soon as possible. A nasoesophageal tube can be used for temporary support for the first few days before general anesthetic for more permanent tube placement. A gastrostomy or esophagostomy tube will usually be required long term because feeding will be necessary in most cases for 4 to 6 weeks. A diet that is as high in protein as possible should be given, preferably managing any resultant encephalopathy by other means such as feeding little and often. This means using a diet manufactured for nutritional support of hypermetabolic sick cats if possible. A diet such as Royal-Canin concentration instant diet or Hill's AD would be suitable. Some clinicians add extra nutrients

- such as taurine, arginine, B vitamins, or carnitine to the tube feed, but there is no firm evidence that any of these are necessary if a balanced feline diet is used.
- Amount to feed: start conservatively with the resting energy requirement (RER) because cats have had prolonged anorexia and complications of feeding are more common in the first few days. Start with small amounts frequently (or even slow-rate constant infusion) and gradually build up to higher volumes and lower frequency over the first week. The calorie intake can then be gradually increased to the metabolic energy requirement (MER).

$$RER = 50 \times BW$$

$$MER = 70 \times BW$$

- Appetite stimulants are not recommended because they are of very limited efficacy and potentially hepatotoxic.
- Additional vitamins are necessary in some cats: cobalamin (vitamin B<sub>12</sub>) may be deficient, particularly in cats with concurrent pancreatic and/or ileal disease (see Chapter 40) and should then be supplemented parenterally. Vitamin K-responsive coagulopathies are very common in cats with lipidosis, and some authors recommend supplementation in all cats at the start of treatment with 0.5 mg/kg given intramuscularly q12h for three doses.
- Antiemetics and promotility agents such as ranitidine (2 mg/kg PO or IV twice a day) and metoclopramide (0.5 mg/kg IM or PO q8h or 1 to 2 mg/kg q24h IV as a slow infusion) may be necessary if the cat is vomiting or has delayed gastric empting with reflux of food up the feeding tube.
- Antioxidants are also recommended, particularly S-adenosylmethionine (20 mg/kg or 200 mg total once a day) on the basis of some limited but supportive evidence in cats. There is currently no evidence in support of the use of ursodeoyxcholic acid in cats with lipidosis.

should be used if necessary. Many cats require vitamin K therapy for coagulopathies [0.5 mg/kg of vitamin K1 (Phytomenadione) subcutaneously or intramuscularly q12h for 3 days]; clinicians should not place any central catheters or invasive feeding tubes until hemostasis is normal. There is the potential for serious and undetected bleeding around a central venous catheter in a cat with a coagulopathy. Antioxidant therapy is also indicated in cats with lipidosis because of the associated glutathione depletion in many cats; vitamin E and S-adenosylmethionie supplementation should be considered. (S-adenosylmethionine: 20 mg/kg once a day given whole on an empty stomach, cats and dogs, or 100- to 400-mg total dose daily in cats. The ideal dose of vitamin E in a cat is unclear, but the authors use 100 IU daily.)

Prognosis for recovery in cats with hepatic lipidosis is reasonably good as long as feeding is rapidly and effectively instituted. Studies have reported between 55% and 80% survival in intensively fed cats, whereas mortality is very high without supportive feeding. One large study (Center et al., 1993) suggested that anemia, hypokalemia, and older age were poor prognostic indicators for survival and that cats with secondary hepatic lipidosis may do slightly worse than those with primary disease. However, the differences were not significant, which suggests that it is well worth treating cats with secondary lipidosis as aggressively as those with primary disease.

## **BILIARY TRACT DISEASE**

Biliary tract diseases are the second most common disorders of the feline liver (see Table 37-1). This contrasts with dogs,

BOX 3*7*-2

## Outline of Method of Placement of Feeding Tubes

#### Nasoesophageal Tube

For short-term nutritional support (<1 week) while stabilizing cat before placement of esophagostomy or gastrostomy tube.

#### Placement

- Premeasure tube to allow placement in caudal esophagus, not stomach; this minimizes gastric reflux. Premeasure to seventh intercostal (IC) space from nose or 75% of distance from nose to last rib if animal is so obese that ribs cannot be counted. (Orogastric: ninth IC space or 90% of distance nose to last rib.) Mark tube with pen or piece of tape.
- Apply local anesthetic to nose. Mild sedation may also be necessary, preferably with buprenorphine or butorphanol, but often not.
- Lubricate tube and advance into ventral meatus; it is important not to advance into middle or dorsal meatus or stops at the ethmoturbinates. It may be helpful to raise cat's head slightly to do this.
- Hold cat's head normally as you approach pharynx to prevent tracheal intubation. Allow cat to swallow, and advance tube to measured mark or tape.
- 5. To check that the tube is correctly positioned, instill water and then air and auscultate over left flank for bubbling in stomach. If still uncertain, perform a radiograph. If tube does not have a radiodense line, inject some ionic contrast material into tube first.
- Pass tube over top of cat's head, and suture or glue tapes at level of nares and top of head; be careful to avoid interfering with cat's whiskers.
- 7. Put on elizabethan collar.
- 8. Flush regularly with warm water before and after feeds.

#### **Gastrostomy Tube**

Indicated for longer-term nutritional support (>1-2 weeks). The tube must be in at least 5 to 7 days for surgical tubes and 14 to 21 days for endoscopically placed tubes to allow adhesions to form between stomach and body wall.

Advantages over nasoesophageal tube of longer-term support: can feed thicker food; better tolerated by animal, which is more likely to start eating with tube in place; easier to manage; could be managed by owner at home. However, it is necessary to use a general anaesthetic for placement.

## Placement at laparotomy

Placement is usually via a left paracostal laparotomy but can be via midline laparotomy.

- Pull stomach to body wall and exteriorize. Pack off area between stomach and body wall.
- Lay two concentric purse-string sutures in greater curvature of body or fundus of stomach, and incise in center of these
- Insert feeding tube or catheter; it is best to use a Pezzar mushroom-tipped catheter and not a foley because the latter show a propensity to disintegrate too early.
- Tighten purse strings; they should be tight enough to seal but not so tight that they cause necrosis of gastric wall.

- Suture stomach to abdominal wall using simple interrupted pattern; you may wrap omentum around tube between stomach and body wall.
- Exit catheter through separate stab incision, and secure to skin.
- 7. Plug to stop air from filling stomach and food from leaking out, and cover with a dressing/body bandage. Put on an elizabethan collar.
- 8. Clean stoma regularly, and flush tube regularly with warm water, even when not in use.

#### Placement endoscopically

This is quicker and less invasive if you are not already doing a laparotomy, but it is necessary to use a fiberoptic endoscope. (However, it is possible to use gastrostomy introducers and do it blind, although there is a higher incidence of traumatic injuries with inexperienced operators, who can easily push the tube through visceral surface of stomach and damage or entrap the spleen. It is best to insufflate stomach first if doing it blind and attempt it only if taught by an experienced operator and practiced on cadavers first.) Several companies make PEG tube kits suitable for veterinary use.

- Clip and aseptically prepare an area of skin caudal to left costal arch.
- Pass endoscope through mouth into stomach and inflate stomach.
- Insert catheter into stomach through stab incision in shaved area of body wall.
- 4. Remove stylet, and pass thick nylon suture through
- Grab suture with biopsy instrument of endoscope, and pull it out of mouth.
- Attach suture to feeding tube as directed by manufacturer.
- Pull the whole assembly back into the stomach by gentle traction on the nylon where it exits the body wall.
- Pull the feeding tube out through the body wall, and secure it with a second stent outside and sutures.
- Cap and cover as directed by manufacturer, and place an elizabethan collar to prevent interference.
- Clean stoma regularly, and flush tube regularly with warm water, even when not in use.

Note on gastrostomy tube removal: Do not remove for at least 5 to 7 days (surgical) or 14 to 21 days (PEG tubes). Method of removal depends on tube placed. Always refer to the manufacturer's instructions, and do not attempt simply to pull the tube out. Most manufactured tube kits for human use cannot be pulled out but have to be cut close to the body wall and the end retrieved from the stomach endoscopically. (The end can be left to pass through into the feces in medium-to large-breed dogs but not cats, in which it may act as a pyloric foreign body.) The Pezzar mushroom-tipped catheters placed surgically can be removed completely by using a stylet in the tube to flatten out the mushroom.

Experience with a trained operator is highly recommended before attempting surgical placement of a gastrostomy tube or blind placement of a gastrostomy tube.

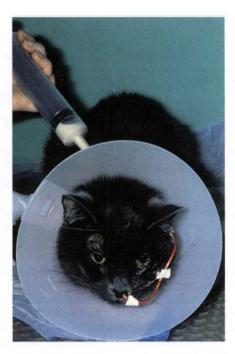

FIG 37-4

in which parenchymal diseases are most common. As discussed in the previous section, cats also often have concurrent pancreatitis and/or intestinal disease; it has been proposed that this is a reflection of the anatomy of their pancreatic and bile ducts, which usually join before entering the proximal duodenum through a common outflow tract (see Fig. 37-1). It has been proposed that this increases the likelihood of intestinal contents being refluxed up both the pancreatic and bile ducts during vomiting. However, it is also possible that the disease associations reflect common causative agents or events independent of the anatomy in this species.

The nomenclature of biliary tract disease has recently been standardized by the World Small Animal Veterinary Association (WSAVA); its recommended categorizations of disease will be used here (Rothuizen et al., 2006; Table 37-3). A wide variety of alternative names have been used in the literature, sometimes blurring the categories and confusing comparisons between studies. It is to be hoped that a standardized nomenclature will aid in the search for causes and treatment of these diseases.

All disorders of the biliary tract in cats can present with very similar clinical signs, including lethargy, anorexia, and jaundice. Clinical, clinicopathologic, and diagnostic imaging findings do not allow differentiation of the types of disease; in most cases, cytology, culture of bile, and histopathology of the liver are necessary for accurate diagnosis and most effective treatment.

#### CHOLANGITIS

Cholangitis refers to inflammation of the biliary tract, which in some (but not all) cats may also extend to the surrounding hepatic parenchyma. It is more common in cats than in dogs, and it is typically divided into three categories, likely associated with different etiologies: neutrophilic cholangitis, lymphocytic cholangitis, and chronic cholangitis associated with liver fluke infestation.

## **Neutrophilic Cholangitis**

Neutrophilic cholangitis is also known as suppurative cholangitis, exudative cholangitis/cholangiohepatitis, and acute cholangitis/cholangiohepatitis.

## **Pathogenesis and Etiology**

This process is believed to be due to an ascending bacterial infection originating in the small intestine. The most common organism isolated is Escherichia coli, although Streptococcus spp., Clostridium spp., and even occasionally Salmonella spp. may be involved. Concurrent pancreatic and intestinal disease are common (as outlined in the preceding sections). The result is a neutrophilic infiltrate in the lumen of the bile duct and often also invasion of the bile duct walls with neutrophils and edema and neutrophils within the portal areas (Fig. 37-6). Occasionally, an associated hepatic abscess may develop. Cholecystitis (inflammation of the gallbladder) may occur concurrently, or the two conditions may occur separately. A more chronic stage of neutrophilic cholangitis is also recognized; in these cases there is a mixed inflammatory infiltrate in the portal areas consisting of neutrophils, lymphocytes, and plasma cells. These cases are thought to represent more chronic, persistent infection of the biliary tract, but there is some overlap with cats with lymphocytic cholangitis according to some studies.

#### **Clinical Features**

Cats of all ages and breeds can be affected, but acute cholangitis is most often seen in young to middle-aged cats. It usually presents acutely (less than a month's history), although the more chronic form may be present for longer.

TABLE 37-3

Outline of Currently Recommended WSAVA Classification of Feline Biliary Tract Disease

NAME OF DISEASE	OLD NAMES PREVIOUSLY USED IN THE LITERATURE	CAUSE OF DISEASE	FINDINGS ON LIVER PATHOLOGY	RECOMMENDED DIAGNOSTIC PROCEDURES
Neutrophilic cholangitis	Suppurative or exudative cholangitis/ cholangiohepatitis Chronic phase: some previously reported cases of "lymphocytic" or "chronic" cholangiohepatitis would now fall into this category.	Likely ascending bacterial infection from small intestine	Acute phase: neutrophils in lumen and/or epithelium of bile ducts. May also be edema and neutrophils in periportal area, parenchyma, and occasionally hepatic abscess.  Chronic phase: mixed inflammatory infiltrate in portal areas, including neutrophils, lymphocytes, plasma cells, and sometimes some fibrosis and bile duct proliferation	Cytology and culture of bile aspirates are necessary for diagnosis. Ultrasound and histopathology can be suggestive but are not obligatory, and changes may be absent on either of these.
Lymphocytic cholangitis	Lymphocytic cholangiohepatitis; lymphocytic portal hepatitis; chronic cholangiohepatitis; nonsuppurative cholangitis: but note overlap of these definitions with the chronic phase of neutrophilic cholangitis	Unknown — may be immune- mediated disease	Infiltration of small lymphocytes into the portal regions. Variable portal fibrosis and bile duct proliferation. Lymphocytes may also be present within biliary epithelium. Occasional plasma cells and eosinophils may be seen. Difficult to differentiate some cases from well-differentiated lymphoma.	Liver histopathology is necessary for diagnosis. Changes may be found on ultrasound and bile cytology but will not give a definitive diagnosis.
Chronic cholangitis associated with liver fluke		Liver fluke	Dilated larger bile ducts with papillary projections and marked periductal and portal fibrosis. Slight to moderate inflammation of portal areas and ducts with neutrophils and macrophages and limited numbers of eosinophils. Flukes and eggs may be seen in ducts.	Ultrasonography of dilated bile ducts + history of possible exposure + demonstration of fluke eggs in feces or bile aspirates (see text). Histopathology supportive.

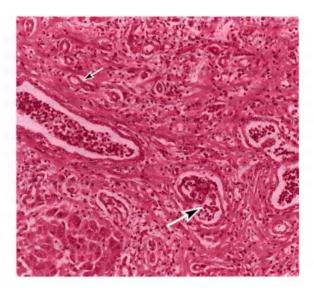

Data from Rothuizen J et al: WSAVA standards for clinical and histological diagnosis of canine and feline liver diseases, Oxford, UK, 2006, Saunders Ltd, Elsevier.

Cats typically have signs of biliary stasis and sepsis with lethargy, pyrexia, and jaundice.

## Diagnosis

Clinicopathologic and imaging findings show overlap with the other diseases of the biliary tract, so a definitive diagnosis of neutrophilic cholangitis cannot be made simply from a characteristic history and clinicopathologic findings. However, cats with this acute disease tend to have higher segmented and band neutrophil counts, ALT activities, and total bilirubin concentrations than cats with lymphocytic cholangitis. They may have a coarse or nodular texture to the liver on ultrasonography and may develop dilated biliary tracts more chronically, but cats with the truly acute disease may have no dilation of the biliary tract on ultrasonography.

An accurate diagnosis of neutrophilic cholangitis caused by acute ascending infection requires cytology and culture of bile. Histopathology of the liver alone is not enough in this particular disease because in many cases the disease is confined to the biliary tract, and changes on liver pathology are mild and nonspecific, Samples of bile for bacterial culture can be taken carefully from the gallbladder during laparotomy or laparoscopy or under ultrasonographic guidance. There is a small but definite risk of bile leakage, particularly if the gallbladder wall is devitalized and/or there is increased pressure within it. In these cases it might be safer to obtain a sample at laparotomy rather than under ultrasonographic guidance. In the latter case a general anesthetic is strongly recommended to prevent patient movement while the needle is in the gallbladder, which greatly increases the risk of bile leakage. The needle should be placed in the gallbladder

Photomicrograph of liver specimen from a cat with neutrophilic cholangitis. Notice the neutrophilic inflammation in and around bile ducts (large arrow). Biliary ductular hyperplasia is also present (small arrow) (hematoxylin-eosin stain).

through the hepatic parenchyma further to reduce the risk of leakage. The cat should be monitored carefully for any leakage of bile after the procedure; any suspicion of leakage and bile peritonitis warrants surgery. Cytology of bile usually shows bacteria and neutrophils, and culture and sensitivity tests should be performed.

## **Treatment and Prognosis**

Cats should be treated for 4 to 6 weeks with an appropriate antibiotic on the basis of the results of culture and sensitivity tests. Amoxycillin is a good initial choice at a dose of 15-20 mg/kg, PO q8h. Ursodeoxycholic acid may be given as an additional choleretic and antiinflammatory agent at a dose of 15 mg/kg, PO q24h, although there are no studies demonstrating their benefit in cats. Septic or extremely sick cats may require hospitalization for intravenous (IV) fluid and IV antibiotic administration during the initial stages of therapy. Careful attention should be paid to feeding anorexic cats to prevent the concurrent development of hepatic lipidosis; a high-protein diet designed for critical care use, as outlined in the lipidosis section, would be much more appropriate in these animals than a protein-restricted liver diet. The prognosis is generally good, and these cats usually recover completely provided they are treated early and appropriately. It is thought that the more chronic form of neutrophilic cholangitis may represent long-term persistence of a lowgrade infection in untreated or only partially treated cats.

### Lymphocytic Cholangitis

Lymphocytic cholangitis is also known as *lymphocytic cholangiohepatitis*, *lymphocytic portal hepatitis*, and *nonsuppurative cholangitis*.

## Pathogenesis and Etiology

Lymphocytic cholangitis is a slowly progressive chronic disease characterized by infiltration of the portal areas of the liver with small lymphocytes. Occasionally, plasma cells and eosinophils may also be seen. There is often associated proliferation of bile ducts, and there may be portal fibrosis. It particularly affects the larger bile ducts, which may become irregularly distended with thickened walls but usually remain patent. In severe cases the main differential diagnosis on histology is lymphoma. The cause is unknown. An immunemediated etiology has been suggested by some researchers, but the disease does not resolve with immunosuppressive medication. Other studies have suggested possible infectious etiologies, such as Helicobacter spp. or Bartonella spp. (Boomkens et al., 2004; Greiter-Wilke et al., 2006; Kordick et al., 1999), although more evidence is required before infectious organisms are confirmed as a cause. However, the use of immunosuppressive medication in these cases is subject to question.

#### **Clinical Features**

Cats with lymphocytic cholangitis are typically young to middle-aged, and Persians appear to be overrepresented. They tend to have a long history (months to years) of waxing and waning low-grade illness. Many become jaundiced, and they often lose weight and have intermittent anorexia and lethargy, but they are less likely to be pyrexic than cats with neutrophilic cholangitis. About a third of cats may also present with a high-protein ascites, reportedly most commonly in the United Kingdom. This makes differentiation from feline infectious peritonitis (FIP) important. Ultimately, the differentiation in these cats can be made only on histopathology.

## **Diagnosis**

Diagnosis in these cases relies ultimately on hepatic histopathology, although ultrasonographic and clincopathologic findings can support a presumptive clinical diagnosis. Increases in liver enzyme activities are mild to moderate and tend to be less marked than in cats with neutrophilic cholangitis. Peripheral blood neutrophilia is less common than in cats with the acute disease but may be present. A particular feature of most cats with lymphocytic cholangitis is an increase in r-globulin concentration, which again may cause confusion with FIP. Radiographic signs are nonspecific: There may be hepatomegaly (which is often due to enlargement of the larger bile ducts) and in some cases ascites (Fig. 37-7). Ultrasonography is more helpful and reveals dilation of the biliary tract in all cases (see Fig. 36-10). The common bile duct typically appears dilated, and there may be dilation of the gallbladder and "sludge" within it. The main differential diagnosis for these cats is extrahepatic biliary obstruction; the ultrasonographer should attempt to rule this out by carefully imaging the surrounding pancreas, small intestine, and mesentery.

It is very important to evaluate a hemostasis profile before performing a liver biopsy in view of how commonly coagulation times are prolonged in cats with liver disease. Vitamin

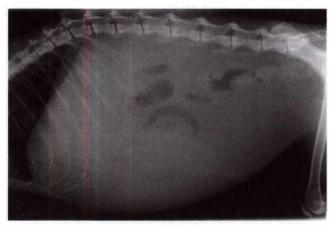

FIG 37-7
A lateral abdominal radiograph from a cat with lymphocytic cholangitis and associated ascites. The major differential diagnosis in this case would be feline infectious peritonitis. (Courtesy the diagnostic imaging department, The Queen's Veterinary School Hospital, University of Cambridge.)

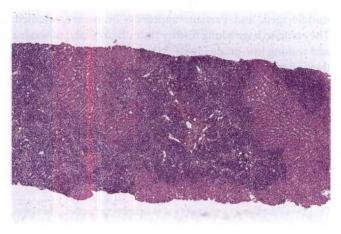

FIG 37-8
Photomicrograph of liver specimen from a cat with severe lymphocytic cholangitis. There is intense mononuclear cell infiltration in the portal tract (center).

K should be given before biopsy (0.5 mg/kg of vitamin K1 SQ or IM q12h for 3 days) if there is any concern about clotting function; fresh frozen plasma should be available to manage postbiopsy bleeding if it occurs. Bile aspiration is not necessary unless the disease is more acute and there is a possibility of neutrophilic cholangitis. Histology is important to rule out FIP (see Chapter 97). The typical hepatic lesion in cats with FIP is a multifocal pyogranulomatous reaction with evidence of vasculitis or perivasculitis, which is quite distinct from the periportal lymphocytic infiltrate seen in cats with lymphocytic cholangitis (Fig. 37-8). Serology or PCR for *Bartonella* spp. might be considered, although the importance of this organism in the naturally occurring disease is unclear.

## **Treatment and Prognosis**

Researchers disagree on the recommended therapy of this disease, which likely reflects our uncertainty about the etiology. A number of authors recommend immunosuppressive doses of corticosteroids. However, although these tend to ameliorate the acute flare-ups of the disease, they do not lead to resolution of signs, and the condition invariably recurs. Antibiotic therapy is wise, at least early in the treatment, until an infectious etiology has been ruled out. There is good logical reason to use ursodeoxycholic acid (15 mg/kg PO q24h) in these cats for its choleretic and antiinflammatory effect as well as its effect on modulating the bile acid pool and reducing toxic bile acids. Use of antioxidants such as S-adenosylmethionine (20 mg/kg or 200 to 400 mg total once a day on an empty stomach) and vitamin E (approximately 100 IU daily) is also logical because bile is a potent oxidizing toxin in the liver. However, none of these therapies has been critically evaluated in cats with lymphocytic cholangitis. Again, it is important to ensure that affected cats eat to prevent the development of concurrent hepatic lipidosis; as discussed in the preceding sections, a highly digestible, high-quality diet without protein restriction is indicated. A diet formulated for feline intestinal disease (such as Iam's feline intestinal or Royal-Canin feline selected protein or Hills ID) might be the most appropriate because of the relatively high prevalence of concurrent inflammatory bowel disease. Tube feeding should be considered if necessary, as outlined in the section on hepatic lipidosis. Cats with more acute signs, particularly associated with concurrent intestinal and/or pancreatic disease, may require hospitalization and IV fluid therapy.

The prognosis for cure appears to be poor because the disease appears to wax and wane chronically in spite of treatment. However, few cats with lymphocytic cholangitis die as a result of their disease. This is likely because, unlike in dogs, the disease does not generally progress to end-stage cirrhosis.

## **Sclerosing Cholangitis**

Sclerosing cholangitis, or biliary cirrhosis, involves an endstage fibrotic liver, and is very uncommon in cats. The condition is characterized histologically by diffuse proliferative fibrosis of bile duct walls spreading to involve the hepatic lobules and disrupting their architecture and circulation. It is thought in most cases to represent an end stage of chronic biliary tract disease: usually complete obstruction or chronic severe liver fluke infestation (see the next section). It is very unusual for neutrophilic or lymphocytic cholangitis to progress to sclerosing cholangitis in cats. Affected cats present with typical clinical signs of chronic biliary tract disease, as outlined in the cholangitis and extrahepatic biliary tract obstruction sections. Affected cats may also develop chronic portal hypertension, with the resultant development of ascites, gastrointestinal ulceration, and/or acquired portosystemic shunts (PSS) and hepatic encephalopathy (see Chapter 39). Acquired PSSs are much less common in cats

than in dogs, although they are occasionally recognized. Sclerosing cholangitis is diagnosed on hepatic biopsy; again, it is very important to evaluate hemostasis profiles before biopsy and to administer vitamin K (0.5 mg/kg SQ or IM q12h for up to 3 days) as necessary because vitamin K deficiency is common in cats with chronic biliary tract obstruction. It should be noted that cats with sclerosing cholangitis may have hepatomegaly on radiography, which is unexpected (cirrhosis usually results in a small liver in dogs). Presumably, this reflects the biliary tract dilation and florid peribiliary fibrosis in these cases. Treatment is supportive, with treatment of only the clinical signs associated with portal hypertension, as outlined in Chapter 39.

## Liver Fluke Infestation

## **Etiology and Pathogenesis**

Liver fluke infestation is regularly observed in cats from areas endemic for the family Opisthorchiidae (Platynosomum spp. and also occasionally Amphimerus pseudofelineus and Metametorchis intermedius). It is estimated that in Florida and Hawaii Platynosomum fastosum (the most common feline liver fluke) has prevalence of up to 70%; the clinical feline disease is referred to as "lizard poisoning." The flukes require two intermediate hosts: water snails and lizards, amphibians, geckos, or fish, depending on the species. The cat is the final host and is infested by ingesting the metacercariae in the second intermediate host. The immature flukes migrate from the intestine to the liver via the bile ducts and become adult and patent by 8 to 10 weeks. Eggs can then be found in the feces (inconsistent) or bile aspirates (more reliable). The severity of associated disease seems to depend on the parasite load and on individual responses. Many cases are mild. In some cases the pancreas may also be affected. The clinical signs are caused by peribiliary inflammation and fibrosis in the liver, culminating, in severe cases, in effectively a posthepatic jaundice. The fluke takes 8 to 12 weeks from infestation to reach adulthood. In experimental infestations hepatic lesions are visible histologically from 3 weeks postinfestation. There is an initial distention of proximal bile ducts and a neutrophilic and eosinophilic inflammatory response, which progresses chronically to adenomatous hyperplasia of ducts and surrounding florid fibrosis. Eosinophils may be absent in the later stages of disease, and flukes and eggs may not be seen on histology.

## **Clinical Signs**

Commonly, cats with low-grade infestations remain asymptomatic. However, heavy infestations can be associated with severe and often fatal disease (Haney et al., 2006; Xavier et al, 2007). In these cases clinical signs are typically those of posthepatic jaundice combined with inflammatory liver disease (e.g., jaundice, anorexia, depression, weight loss, and lethargy). Diarrhea and vomiting have been features of clinical cases but do not occur in experimental cases; affected cats may also have hepatomegaly and ascites.

### Diagnosis

Diagnosis is made after a history of exposure (cats often have a history of hunting lizards) combined with finding the flukes or eggs in feces and bile. Supportive findings are high liver enzyme activities typical of cholestasis; ALT and AST activities and bilirubin concentration are particularly high, but ALP activity is surprisingly often only mildly elevated. Eosinophilia may be seen in severe cases but is inconsistent. Ultrasonography reveals changes typical of biliary tract disease, such as dilation of the bile ducts. In one case fluke infestation also caused acquired polycystic disease of the biliary system (Xavier et al., 2007).

Ova may be found in the feces using the formalin-ether sedimentation method (Box 37-3). However, shedding of eggs is sporadic; also, of course, eggs will not be present if the fluke infestation has resulted in a complete biliary obstruction. The most reliable way of demonstrating flukes and eggs is on bile aspirates.

## Treatment

The ideal and most effective treatment regimen for feline liver flukes remains controversial. Currently, the most commonly recommended treatment is praziquantel at 20 mg/kg SQ q24h for 3 days. The prognosis for recovery in severely affected cats is poor.

## **CHOLECYSTITIS**

Cholecystitis refers to inflammation of the gallbladder. Neutrophilic cholecystitis is frequently seen in cats but rarely in

BOX 37-3

Formalin-Ether Sedimentation Technique for Detecting Platynosomum concinnum Ova in Feces

- Mix 1 g of feces in 25 ml saline; filter through a fine mesh screen.
- 2. Centrifuge solution for 5 min at 1500 rpm; discard the supernate.
- Resuspend the pellet with 7 ml of 10% neutral buffered formalin; let stand for 10 min.
- Add 3 ml of cold ether on top of solution and shake vigorously for 1 min. Centrifuge for 3 min at 1500 rpm.
- Discard the supernate, resuspend the pellet in several drops of saline, and prepare slide of solution to examine microscopically.

dogs. It may occur alone or in combination with neutrophilic cholangitis. Ultrasonographically, the gallbladder wall often appears thickened and sometimes irregular; there may be "sludging" of the bile and/or choleliths. Clinical signs, diagnosis, and treatment are very similar to those of neutrophilic cholangitis (see preceding section). Lymphocytic cholecystitis is also occasionally recognized.

### **BILIARY CYSTS**

Most cystic lesions in the feline liver are of bile duct origin and may be congenital or acquired. Congenital cysts are usually multiple and often present as part of a polycystic disease of several organs, including the kidneys. The cystic contents are clear. Persian cats and Persian crosses are at increased risk. Cysts may be an incidental finding on imaging, particularly if they are small, but large cysts can cause clinical signs as a result of destruction of hepatic tissue and also compression of surrounding bile ducts resulting in signs of biliary tract obstruction (see next section). Treatment is not indicated if they are small and nonprogressive, but if they are large and causing problems, they may be treated surgically by removal or omentalization (Friend et al., 2001).

Acquired hepatic cysts may be single or multiple and may be small or very large. The contents may be clear, bloody, or bilious. They may occur secondary to trauma, inflammation, or neoplasia (including biliary cystadenomas) or in rare cases caused by liver flukes. Therapy depends on the cause, but surgical management may be necessary if they are large.

## EXTRAHEPATIC BILE DUCT OBSTRUCTION

## Pathogenesis and Etiology

Extrahepatic bile duct obstruction (EBDO) is a syndrome associated with several different underlying causes. Causes of EBDO may be categorized as extraluminal compressive or intraluminal obstructive lesions, but often diseases cause EBDO through a combination of these mechanisms (e.g., cholangitis may result in a combination of extraluminal compression by associated edema and inflammation and intraluminal obstruction by inspissated bile). Therefore it is more practically helpful to divide the causes into common and less common causes (Box 37-4). Several studies have shown inflammation of the small intestine, pancreas, biliary tract, or a combination of these ("triaditis") to be the most common cause of EBDO in cats; neoplasia of the biliary tract or pancreas are the next most common cause. Choleliths are very uncommon in cats. Those reported in the literature are usually cholesterol or calcium salts or a mixture of these and are associated with cholangitis. They are variably radiodense depending on the amount of calcium in the stone, but they are easily visualized with ultrasonography of the biliary tract. Two out of the three cases of bilirubin choleliths reported in the literature were from Somali cats with pyruvate kinase deficiency, and it was assumed that they were secondary to hemolysis (Harvey et al., 2007). Therefore finding bilirubin

Causes of Extrahepatic Bile Duct Obstruction (EBDO) in Cats

#### Common Causes

- One or a combination of inflammation of pancreas, duodenum, or biliary tree (most common)
- Neoplasia, particularly of the biliary tree or pancreas (second most common)

#### **Less Common Causes**

- Stricture of bile duct after inflammation, surgery, or trauma
- Diaphragmatic hernia with involvement of the gallbladder/common bile duct and subsequent compression
- Cholelithiasis
  - Usually cholesterol and/or calcium salts secondary to cholangitis
  - Occasionally bilirubin—associated with pyruvate kinase deficiency-induced hemolysis in Somali cats
- Cysts (congenital or acquired) compressing biliary tree
- Liver flukes

Note that sepsis distant to the liver can produce an associated biliary stasis, which may appear clinicopathologically to be very similar to EBDO.

Note also that biliary tract rupture (usually traumatic) produces similar clinicopathological findings to EBDO.

choleliths in a cat should stimulate a search for underlying hemolytic disease.

#### **Clinical Features**

In case series of cats with EBDO, clinical signs, clinicopathologic findings, and survey radiographic findings were indistinguishable from those associated with other severe cholestatic hepatopathies; jaundice, anorexia, depression, vomiting, and hepatomegaly were the main presenting features. If biliary obstruction is complete, feces will be pale or acholic. There may be a cranial abdominal mass on palpation, because of either a very distended gallbladder or underlying neoplasia, but often abdominal palpation is normal (other than the hepatomegaly). Cats with EBDO are at particular risk of malabsorption of fat-soluble vitamins, including vitamin K, because of the lack of intestinal bile salts reducing fat digestion. This is compounded in many cases by the concurrent intestinal and/or pancreatic disease, which further reduces fat absorption. As discussed previously, it is very important in these cases to assess coagulation times before performing biopsies or surgery and to supplement vitamin K parenterally as necessary.

#### Diagnosis

Ultrasonography is the most useful diagnostic tool to differentiate EBDO from other biliary tract diseases in cats; sometimes, the cause of EBDO is determined. Clinicopatho-

logic findings are nonspecific; the high concentration/activities of hepatocellular and biliary enzymes, bilirubin, and cholesterol resulting from cholestasis are indistinguishable from those in cats with other severe cholestatic hepatopathies. Ultrasonography will usually reveal dilation of the gallbladder and the extrahepatic and intrahepatic biliary trees, although gallbladder dilation is not a consistent and essential finding. A search should then be conducted for a possible cause of obstruction by carefully examining the small intestine, liver, and pancreas for evidence of inflammation or neoplasia. Biliary tract rupture can present in a similar way and should be ruled out by identifying and analyzing any free abdominal fluid; cats with biliary rupture have a high concentration of bilirubin in the fluid. FNA of bile from the gallbladder under ultrasonographic guidance should be avoided or approached with great care if EBDO is suspected or confirmed because there is a high risk of leakage on account of the increased pressure. In these cats it is preferable to aspirate bile during surgery. It may be necessary to undertake an exploratory laparotomy to assess bile duct patency and the cause of the obstruction. Hemostatic function should be assessed first, and vitamin K therapy given as 0.5 mg/kg of vitamin K<sub>1</sub> SQ or IM q12h for 3 days. The liver, pancreas, and small intestine should be carefully inspected and biopsied, as deemed necessary.

#### **Treatment**

Treatment depends on the underlying cause of the EBDO and whether the obstruction is complete or partial. Biliary tract surgery in the cat carries a high morbidity and mortality and should be undertaken only when necessary to relieve complete obstruction. The prognosis for partial obstructions is surprisingly good when using medical management, and surgery may not be necessary in all cases. Recent studies of EBDO in acute-on-chronic pancreatitis in humans suggest that medical management rather than surgery or stenting is the treatment of choice in most cases and that there are usually no long-term sequelae. Similar studies have not been reported in cats.

If the feces are not acholic and there is some evidence of bile flow into the duodenum, cats can be managed medically with a choleretic (ursodeoxycholic acid 15 mg/kg PO q24h) and an antioxidant such as S-adenosylmethionine (20 mg/kg or 200 to 400 mg daily on an empty stomach) to protect the hepatocytes against bile-induced oxidant damage. The underlying disorder should also be treated as outlined in the preceding section. However, if the cat does not improve after several days or signs of complete obstruction, such as acholic feces, develop, surgical intervention is indicated. If the cat requires cholecystoenterostomy, the prognosis is poor.

## HEPATIC AMYLOIDOSIS

#### Etiology

Hepatic amyloidosis is an uncommon but apparently emerging cause of liver disease in cats. Historically, amyloidosis has

been recognized most commonly as a familial disease in Siamese cats with both renal and hepatic involvement. Abyssinian cats also suffer from familial amyloidosis, but it is predominantly renal in this breed. However, more recently it has been reported sporadically in a number of breeds, including domestic short-haired cats with purely hepatic and no renal involvement (Beatty et al., 2002). The amyloid in both familial and sporadic cases is amyloid A (inflammatory), and in sporadic cases there is usually an underlying chronic inflammatory process in another organ (such as chronic gingivitis) thought to be the driving force for the formation of the inflammatory amyloid.

## **Clinical Signs and Diagnosis**

Affected cats usually present with signs of anemia and hypotension related to rupture of the hepatic capsule and hemoabdomen. These cats are predisposed to hepatic rupture because the liver is enlarged and also rigid and therefore easily damaged with normal trauma such as knocking the abdomen when jumping. Affected cats usually exhibit lethargy, anorexia, pale mucous membranes, a bounding pulse, and a heart murmur secondary to the anemia but rarely any specific signs of liver disease. There may be hepatomegaly on abdominal palpation.

## **Diagnosis**

Diagnosis relies on histopathology of a liver biopsy; although clinicopathologic and ultrasonograhic findings are supportive, it is important to rule out the major differential diagnoses of FIP, hepatic lipidosis, and hepatic lymphoma. The transient anemia resolves as blood is reabsorbed from the abdomen (autotranfusion). There are mild to marked increases in ALT activity and globulin concentration but rarely increases in ALP and GGT activities, which helps differentiate amyloidosis from biliary tract disease and lipidosis. On ultrasonography amyloidosis can resemble both lymphoma and lipidosis, with hepatomegaly and a generalized increase in hepatic parenchymal echogenicity or mixed hypo- and hyperechoic appearance (Beatty et al, 2002), but no dilation of the biliary tract. FNA cytology is not helpful because amyloid does not appear on the aspirate. Therefore hepatic biopsy, after careful evaluation of hemostasis profiles, is the recommended method of diagnosis.

### **Treatment and Prognosis**

Treatment is supportive because there is no specific antiamyloid medication. Colchicine is of uncertain efficacy and is not indicated in cats because of its potential toxicity. Instead, the focus should be on reducing or eliminating the underlying inflammatory disorder driving the amyloid deposition, and supportive care with antioxidants and vitamin K supplementation as necessary (0.5 mg/kg SQ or IM every 7 to 20 days). Blood transfusions may be necessary in cats with acute hemoabdomen. The long-term prognosis is poor, and most cats die as a result of intraabdominal bleeding.

## **NEOPLASIA**

## Etiology

Primary liver tumors are uncommon in cats but are nevertheless more common than in dogs. Hepatic tumors are much less common in both species than they are in people, possibly because two of the predisposing factors for development of liver tumors (hepatitis virus infection and α-protease inhibitor deficiency) have not been recognized in small animals. Cirrhosis also predisposes to liver tumors in people but is rare in cats. Liver tumors represent 1% to 2.9% of all neoplasms in cats (Liptak, 2007) but up to 6.9% of the nonhematopoietic tumors. No predisposing factors have been identified. In contrast to dogs, benign tumors are more common than malignant tumors in cats; they may be an incidental finding during workup for other diseases. An unusual benign tumor occasionally found in cats is the myelolipoma, which has a suggested association with chronic hypoxia and hepatic involvement in diaphragmatic hernias. Biliary carcinomas are the most common malignant tumors in cats; this may mirror the high prevalence of biliary tract disease in this species. Trematodes are also a predisposing cause in humans and may be in some cats, but bile duct carcinomas also occur in cats outside the range of liver fluke infestations, so there are obviously other factors involved. Also in contrast to dogs, primary hepatobiliary tumors are more common than metastatic neoplasia in cats. Secondary tumors include particularly hematopoietic tumors, such as lymphoma and, less commonly, leukemias, histiocytic tumors, and mast cell tumors and metastases from other organs such as the pancreas, mammary glands, and gastrointestinal tract. Hemangiosarcomas in the liver may be primary or secondary, and sometimes the origin is difficult to ascertain if multiple organs are involved, although primary hepatic hemangiosarcomas appear to be more common in cats than in dogs.

The common feline primary liver tumors recognized and their behavior are outlined in Table 37-4.

#### **Clinical Features**

Primary malignant liver tumors are usually seen in older cats (mean age 10 to 12 years). There is no obvious gender predisposition reported. The presenting clinical signs and clinicopathologic findings are indistinguishable from those in cats with other primary liver diseases. There may be lethargy, vomiting, weight loss, ascites, or jaundice. Some affected cats may have palpable hepatomegaly, ascites, or liver masses on abdominal palpation. However, at least 50% of cats with liver tumors are asymptomatic.

## Diagnosis

Diagnosis relies on a combination of diagnostic imaging, cytology, and histology. A suspicion may be gained from the clinical findings, but given that more than half of affected animals have no clinical signs, the liver mass may be a serendipitous finding while the cat is being imaged for another reason. On clinical pathology high liver enzyme activity and bile acid concentration and mild anemia and neutrophilia are common but nonspecific findings. Jaundice is uncommon but can occur. Liver function is usually normal because the tumor must involve more than 70% of liver mass before resulting in a reduction in liver function. The exception to this is diffuse hematological malignancy (e.g., lymphoma), which can result in significant disturbance of hepatocyte function (including coagulopathies). The functional defects often resolve when the tumor is cytoreduced by chemotherapy.

Radiographs may show hepatomegaly; the liver may have an irregular border or focal enlargement of one lobe. There may be also involvement of other organs (e.g., lymphadenopathy in cats with lymphoma), and thoracic radiographs may reveal evidence of metastases. However, radiographs

**TABLE 37-4** 

**Primary Liver Tumors in Cats** 

### TYPE OF TUMOR

Bile duct tumors:

Biliary carcinoma (including cystadenocarcinoma)

Biliary adenoma

Gallbladder tumors

Hepatocellular tumors:

Hepatocellular carcinoma (HCC)

Hepatocellular adenoma (hepatoblastoma-very rare)

Neuroendocrine tumors:

Hepatic carcinoid

Primary hepatic sarcomas:

Hemangiosarcoma, leiomyosarcoma, and others

#### BEHAVIOR

Most common primary liver tumor in cats (>50%).

Biliary carcinoma most common malignant feline liver tumor. Aggressive behavior—diffuse intraperitoneal metastases in 67% to 80% of cases.

Recognized but less common than biliary tumors. Adenoma more common than carcinoma.

Very rare but very aggressive

Uncommon. Most locally aggressive and high MR.

Hemangiosarcoma most common primary hepatic sarcoma in cats.

Note: Benign tumors are more common than malignant tumors in this species. MR. Metastatic rate.

may also be normal. Some malignant hepatic tumors commonly metastasize to the peritoneum and local lymph nodes and less commonly to the lungs. As in other diseases of the liver, ultrasonography is more helpful in identifying a hepatic mass and also in evaluating for metastases; it also allows for FNA of the mass(es). Hepatic tumors can also be cystic, particularly cystadenocarcinomas. Cats, unlike dogs, rarely have benign nodular hyperplasia in the liver, so this is not a differential diagnosis for a hepatic mass. Diffuse hepatic tumors (e.g., lymphoma) may show a diffuse change in echogenicity, or the liver may appear normal on ultrasonography. Important differential diagnoses for diffuse hepatic tumors are FIP, lipidosis, and amyloidosis. A thorough abdominal ultrasonographic examination should be undertaken to search for evidence of metastases. It should be kept in mind that because benign tumors are more common than malignant tumors in cats, no animal should be euthanized on the basis of finding a hepatic mass with no evidence of metastases on ultrasonography.

A definitive diagnosis is usually obtained using cytology or histopathology. In some cases FNAs may be diagnostic, but in others they may be difficult to interpret, particularly in cats with benign hepatocellular tumors, in which the cells look indistinguishable from normal hepatocytes. Ultrasonography-guided Tru-Cut biopsies are usually diagnostic; alternatively, biopsies can be obtained during laparoscopy or laparotomy. In the case of an apparently single lesion, the clinician may elect to proceed straight to surgical removal and an "excisional" biopsy. Hemostasis profiles should be evaluated before performing a biopsy. It is unusual for the one-stage prothrombin time and activated partial thromboplastin time to be prolonged in cats with primary liver tumors, but they can be markedly prolonged in cats with diffuse hepatic infiltration with lymphoma or other diffuse secondary tumors (e.g., mast cell tumors). Biopsies should not be considered in these cases until clotting factors have been replenished with a fresh frozen plasma transfusion.

#### **Treatment**

Treatment of primary hepatic tumors relies on surgical removal if they are resectable. This is advisable even in cats with benign tumors, including biliary adenomas. Treatment of diffuse, nodular, or metastatic tumors may be difficult. Primary hepatic tumors generally have a poor response to chemotherapy. It has been suggested that this is because hepatocytes, both normal and transformed, have high expression of the multidrug resistance membrane-associated P-glycoprotein and also that hepatocytes are naturally high in detoxifying enzymes. Radiotherapy is not wise because normal liver tissue is very radiosensitive. For additional information, please see Chapters 80 (the section on lymphoma) and 82 (the section on mast cell tumors).

#### **Prognosis**

Prognosis of benign tumors is good after resection. Prognosis is very poor for cats with any type of malignant liver

tumor; however, most cats with lymphoma of the liver respond to chemotherapy (see Chapter 80).

## **CONGENITAL PORTOSYSTEMIC SHUNTS**

## **Etiology and Pathogenesis**

PSSs are abnormal vascular communications between the portal and systemic circulation. They may be congenital or acquired secondary to portal hypertension. Those of the latter type are usually multiple vessels and are very rare in cats because they usually occur secondary to severe hepatic fibrosis and cirrhosis, both uncommon in cats. Acquired PSS secondary to a congenital hepatic arteriovenous (AV) fistula has been reported in a young cat, but this is very rare (McConnell et al., 2006). Most cases of PSS in cats are therefore congenital, but even these are recognized less commonly than in dogs. Congenital PSSs are usually single or at most double vessels and may be intrahepatic or extrahepatic in location. Cats may have either type of PSS (Lipscomb et al., 2007). Extrahepatic PSSs represent abnormal communcations between the portal vein or one of its contributors (left gastric, splenic, cranial, or caudal mesenteric or gastroduodenal veins) and the caudal vena cava or azygos vein. Intrahepatic PSSs may be left-sided, in which case they are believed to represent a persistence of the fetal ductus venosus after birth (patent ductus venosus, PDV; White and Burton, 2001), or they may be right-sided or centrally located in the liver, in which case they are believed to be anomalous vessels. The reason that congenital PSSs develop at all is unknown, although it is assumed that there may be genetic reasons and/or developmental problems in utero that resulted in abnormal development of the liver vasculature.

The pathophysiology of congenital PSS largely relates to the shunting of unfiltered blood directly into the systemic circulation, resulting in hyperammoniemia and hepatic encephalopathy (HE). The pathophysiology of HE is outlined in Chapter 35. The shunting vessel acts as a lowresistance pathway for some of the portal blood, bypassing the higher resistance intrahepatic portal vasculature. Portal pressure is therefore lower than normal in cats with congenital PSS, which is an important distinguishing feature from (rare) cases of acquired shunting, in which there is portal hypertension and therefore an increased portal pressure. Concurrent hepatic microvascular dysplasia or portal vein hypoplasia, which can confuse this differentiation, occurs in some dogs (see Chapter 38) but has not been reported in cats. Shunting may also allow bacteremia and potentially infections of hematogenous origin that may present as "pyrexia of unknown origin," although this is rare. Additional effects of portal blood bypassing the liver are hepatic atrophy and a reduction in the metabolic activity of the liver, which contributes to inefficient use of dietary components, poor growth, and loss of lean body mass.

Liver atrophy (microhepatia) and changes in hepatic organelle function are partly due to changes in hepatic per-

fusion. The portal blood usually provides about 50% of the liver's oxygen requirement, but this is obviously reduced in cats with PSS. Cats with PSS typically have arteriolar hyperplasia in an attempt to compensate for the reduced portal flow, but they often still have some degree of hepatic underperfusion. In addition, PSS results in reduced delivery of "hepatotrophic factors," such as insulin, to the liver, which further contributes to hepatic atrophy.

## **Clinical Features**

Persian and Himalayan cats have been reported to be at increased risk for congenital PSS in small case series, and another series noted that purebred cats in general were overrepresented; however, cats of any breed, including mixed-breed cats, can be affected. Both sexes appear to be equally at risk. There is no reported associated between breed and shunt types (unlike in dogs), although in one study 6 out of 13 cats with an intrahepatic PSS were Siamese (Lipscomb et al., 2007). Most cases present before 2 years of age; many are younger than 1 year old, but old cats with congenital PSSs are frequently recognized.

The typical clinical signs in cats with congenital PSS are gastrointestinal, urinary, or neurological (HE), although the latter tend to predominate in cats and, anecdotally, are often more severe than in dogs. Cats typically present with a history of waxing and waning neurological signs consistent with HE rather than a sudden acute HE crisis. The typical signs of HE are outlined in Box 35-1. Hypersalivation is a common sign of HE in cats, but it is rare in dogs. There is sometimes an association between HE and feeding, which may relate to glutamine metabolism by enterocytes releasing ammonia, although not all cats display these signs. Cats in acute crisis may present comatose or with seizures; cats appear to be more susceptible to seizures than dogs, both preoperatively and postoperatively. The reason for this is unknown, although it has been suggested that sudden changes in the concentrations of ammonia and other metabolites in the blood after surgery or sudden changes in medical management may destabilize neurotransmitters in cats. Drug intolerance is common, particularly prolonged recovery from routine anesthesia for spaying/neutering. Animals with PSS may also show intermittent vomiting and/or diarrhea. Urinary tract signs are due to cystitis associated with urate calculi and polyuria/polydipsia, but they are less common in cats than in dogs. Impaired urine-concentrating ability may reflect reduced renal-concentrating gradient secondary to low urea concentration and increased blood cortisol concentration secondary to reduced hepatic breakdown, although this has been demonstrated only in dogs thus far. Cats with congenital PSS also often (but not always) show signs of poor growth compared with their littermates (Fig. 37-9). There has been a reported high prevalence of coppercolored irises in cats with PSS (see Fig. 37-9), but this is not a consistent feature.

Because of the low portal pressure, ascites is not a feature in cats, which helps in distinguishing congenital PSS from

A 6-month-old kitten with a congenital portosystemic shunt, demonstrating very small size for its age and also coppercolor irises, which are often noted in kittens with portosystemic shunts.

the rare feline cases of acquired PSS, in which ascites is more common because of portal hypertension.

## **Diagnosis**

A suspicion for congenital PSS can be gained from the history of recurrent neurological signs combined with high fasting and/or postprandial bile acid or ammonia concentrations. Care should be taken when performing traditional ammonia tolerance tests, which can precipitate severe HE. Postprandial ammonia or bile acid determinations are safer alternatives. Serum bile acid concentrations should be measured before and 2 hours after feeding. (see Box 36-1). If ammonia is measured instead, the postprandial sample should be taken 6 hours after feeding (Walker et al., 2001). Other typical (but not pathognomonic) clinicopathologic findings in some (but not all) cats include low serum urea concentration, mildly increased liver enzyme activities, and microcytosis. Notable differences from dogs are that decreases in total protein or albumin concentrations, hypoglycemia, and anemia are much less common in cats. Urine specific gravity is low in many dogs but occurs in fewer than 20% of affected cats. If fasting bile acid concentrations are very high, it is not necessary to obtain a postprandial sample, but the diagnostic sensitivity of doing both is higher than just measuring fasting concentrations. If biliary stasis (which also causes high bile acid concentrations) is ruled out and the cat does not have hepatic lipidosis (which causes hepatocellular failure and HE with increases in bile acid and ammonia concentration in many cases), it is likely that the cat has a congenital PSS because other causes of HE and high bile acid concentrations are uncommon in cats. Abdominal radiographs show a small liver in 50% of cases (Lamb et al., 1996). However, for definitive diagnosis the shunting vessel must be visualized.

Visualization of the shunting vessel is achieved by ultrasonography or portal venography (see Fig. 36-7, A and B) Transcolonic portal scintigraphy will also demonstrate portosystemic shunting, but it does not differentiate congenital from acquired shunting. A liver biopsy should be taken at the time of surgery or portovenography (after evaluation of hemostasis profiles) to rule out other or concurrent conditions. This shows histological features very similar to those in dogs and typical of portal venous hypoperfusion with loss of smaller portal veins, increased numbers of arterioles, hepatocellular atrophy with lipogranulomas, and sometimes periportal sinusoidal dilation but minimal inflammation.

#### **Treatment**

Treatment involves complete or partial ligation of the shunting vessel using one of several methods, including silk or cellophane or ameroid constrictors; a detailed explanation is beyond the scope of this book. The procedure is best reserved for referral centers, particularly in cats, which are more prone to complications than dogs. The postoperative mortality in cats appears to be higher than in dogs, which is often due to intractable severe neurological signs. Pretreatment with phenobarbital has been attempted, but too few cases have been reported to assess its value. Propofol infusions are often used for HE-associated seizures in dogs, but care must be taken in cats because of their susceptibility to Heinz body anemia when given propofol infusions.

Cats should be managed medically before and for a period of about 2 months after surgery while the portal vasculature and liver mass recover. This involves careful mild dietary protein restriction with additional antibiotics (usually amoxicillin, 15 to 20 mg/kg PO q8h) and sometimes also a soluble fiber source such as lactulose (2.5 to 5 ml, given PO q8h to effect). Some anecdotal data suggest that changes in medical management should be made more gradually in cats than in dogs to prevent the risk of seizures (e.g., change the diet first, then add antibiotics after a week or more, and then add the soluble fiber source later). Details of medical management of HE are described in Chapter 39. Cats do not tolerate marked dietary protein restriction because of their high obligate protein requirement (see Table 37-2). A diet manufactured for cats with liver disease (such as Hills LD) is appropriate, and, unlike in dogs, home-made diets based on dairy protein should be avoided in cats because dairy protein is relatively deficient in arginine, which is essential for the urea cycle; deficiency will further predispose to hyperammonemia. Medical management alone is effective in some dogs long term (see Chapter 38), but anecdotally, cats do not do as well with medical management of congenital PSS, probably because of their high obligate protein metabolism, which would make them more susceptible to hyperammonemia, regardless of the diet fed.

#### **Prognosis**

The prognosis appears to be good if the PSS can be ligated, although insufficient cases have been reported to assess the

## Infectious Diseases with Hepatic Involvement in Cats

Liver fluke (see text for details)
Feline infectious peritonitis
Toxoplasmosis
Bartonellosis
Histoplasmosis
Tyzzer's disease
Salmonellosis

Infection with *Streptococcus* groups B and G in neonates Leptospirosis (extremely rare)
Disseminated mycobacterial infections
Infection with *Cytauxzoon felis* 

Tularemia (Francisella tularensis)

Note also that neutrophilic cholangitis is often due to ascending bacterial infection from the gut. *Bartonella* spp. may be involved in the etiology of some cases of lymphocytic cholangitis.

long-term prognosis. However, clients should be warned that short-term mortality rate after surgery is relatively high.

#### HEPATOBILIARY INFECTIONS

Several infectious organisms can infect the liver, either as a primary target or as part of a more generalized infection. These are listed in Box 37-5. In addition, neutrophilic cholangitis likely has a primary infectious cause in most cats (discussed in more detail in a previous section).

Hepatic involvement is common in both the dry and effusive forms of FIP (see Chapter 97). Because cats with effusive FIP can present with the same signs as cats with lymphocytic cholangitis, it is an important differential diagnosis for this disease. A liver biopsy may be necessary to distinguish them; a diagnosis is occasionally made cytologically.

Disseminated toxoplasmosis is uncommon in cats, but when it occurs, the liver is usually involved with intracellular growth of Toxoplasma gondii during the active clinical disease, resulting in cell death. Effects of delayed hypersensitivity reactions and immune-complex vasculitis also contribute to clinical illness. Infection of the lungs, liver, and central nervous system (including the eyes) with trophozoites is most commonly responsible for clinical signs. As expected, high serum ALT activity and hyperbilirubinemia commensurate with the degree of hepatocellular necrosis are the typical serum biochemical findings in cats with liver involvement. Cholangiohepatitis resulting from infection of the biliary epithelium has been noted occasionally in experimental and spontaneously occurring cases of toxoplasmosis in cats. The distribution of affected tissues in disseminated histoplasmosis often includes the lung, eye, bone marrow, spleen, lymph node, skin, bone, and liver. Infection with Bartonella spp. can cause cholangitis in cats.

## TOXIC HEPATOPATHY

## **Pathogenesis and Etiology**

By definition, toxic hepatopathy refers to a hepatic injury directly attributable to exposure to environmental toxins or certain therapeutic agents. Any therapeutic agent could potentially be heptatotoxic as a result of an idiosyncratic reaction, but only a limited number of such drugs have been reported in cats (Box 37-6) in addition to reported environmental hepatotoxins. Cats are particularly sensitive to phenol toxicity because of their limited hepatic glucuronide transferase activity. A variety of essential oils used topically have been reported to be hepatotoxic in cats. Essential oils are absorbed rapidly, both orally and dermally, and are metabolized by the liver to glucuronide and glycine conjugates; it is believed that cats are more sensitive than dogs to their hepatotoxic effects (Means, 2002).

Complete information that could support meaningful conclusions about the frequency, character, and substances that consistently cause hepatotoxicity in cats is not available. Clinicians therefore must rely on anecdotal reports, clinical observations, and data accumulated by central agencies such as the National Animal Poison Control Center in Urbana, Illinois (888-426-4435; \$55 per case via credit card), and the U.S. Food and Drug Administration's Center for Veterinary Medicine, in Washington, DC (the toll-free telephone number for reporting suspected adverse drug experiences is 1-888-FDA-VETS). In general, drug- or toxin-induced hepatic injury in cats is extremely uncommon, and most reactions are acute (occuring within 5 days of exposure). The character and severity of the toxic reaction depend on the characteristics of the substance, as well as the dose and the duration of exposure.

Three therapeutic agents have been reported to be hepatotoxic in certain cats: tetracycline (1 cat), diazepam (17 cats), and stanozolol (16 cats). Veterinarians have used these agents for years without known deleterious effects. For each drug, clinical and clinicopathologic signs of hepatotoxicosis developed within 13 days of daily oral administration at recommended dosages. The adverse hepatic reaction to tetracycline was serious but nonlethal, and the cat recovered completely after drug discontinuation and 6 weeks of supportive care (Kaufman et al., 1993). Histologic findings in the liver included centrilobular fibrosis, mild cholangiohepatitis, and mild lipid deposition in hepatocytes. In the cats that experienced diazepam-associated hepatic failure, the outcome was death in 16 of 17 despite intensive treatment. The oral dosages of diazepam that cats received, primarily for inappropriate urination, ranged from 1 mg every 24 hours to 2.5 mg every 12 hours. The histologic lesions in the liver were similar to those observed in the cat with tetracycline-associated hepatic injury but more severe: massive, predominantly centrilobular necrosis; suppurative cholangitis; and mild lipid vacuolation in some cats. Because of the severity of the lesions reported in cats apparently susceptible to diazepam-associated hepatic necrosis, serum liver enzyme activities should be evaluated during the window of days 3

Aflatoxin

Dry-cleaning fluid (tricholorethane)

Toluene

**Phenols** 

to 5 of administration in cats given diazepam by mouth. Until there is more information that would improve understanding of this lethal and unpredictable hepatic reaction, use of other agents for control of behavior and elimination problems in cats is recommended. Cats that experienced an adverse reaction to stanozolol were healthy or had chronic renal failure (14 of 18 cats) or gingivitis/stomatitis (2 of 3 cats; Harkin et al., 2000). Serum ALT activity was markedly increased in most cats given 1 mg orally every 24 hours for several months or 4 mg orally every 24 hours (and 25 mg intramuscularly once) for 3 weeks; all but one survived after the drug was discontinued and intensive supportive care given. The histologic lesions were moderate to marked, diffuse centrilobular lipidosis and evidence of intrahepatic cholestasis (accumulation of bile and lipofuscin in hepatocytes and Kupffer cells).

The new microsomal triglyceride transfer protein (MTP) inhibitors marketed for weight loss in dogs are known to increase liver enzymes reversibly in that species but could result in clinically significant hepatic lipidosis in cats if used off-label in that species. This has not been reported yet because their use in cats is specifically contraindicated; however, clinicians should be aware of the risk.

The discriminatory eating habits of cats may account for the relatively uncommon occurrence of hepatotoxicity from ingested environmental toxins such as pesticides, household products, and other chemicals. It is certainly possible that many adverse hepatic reactions to drugs or toxic chemicals go unnoticed in cats because the first clinical signs of illness are vomiting and diarrhea, after which the medication is stopped. If the signs resolve, there usually is no further evaluation and the medication is not readministered to prove that the substance caused the reaction.

## Diagnosis

Clinical evidence that suggests drug- or toxin-induced hepatic damage includes supportive history (e.g., known exposure); normal liver size to mild generalized tender hepatomegaly; laboratory test results consistent with acute liver injury (e.g., high serum ALT and/or AST activity, hyperbilirubinemia); and, if the exposure was nonlethal, recovery with discontinuation of the agent and specific or supportive care. There are no pathognomonic histologic changes in the liver, although necrosis with minimal inflammation and lipid accumulation are considered classic findings. In many cases all clinical and clinicopathologic markers of a toxic liver insult are present, but the inciting chemical cannot be identified. In the case of hepatotoxicity from therapeutic agents, idiosyncratic reactions can occur that are not dose related, although drug overdose is usually the reason for liver injury.

#### **Treatment**

In cats with suspected acute hepatotoxicity, the basic principles for treatment of toxicoses are applied: preventing further exposure and absorption, managing life-threatening cardiopulmonary and renal complications, hastening elimination of the substance, implementing specific therapy if possible, and providing supportive care. Because few hepatotoxins have specific antidotes, the success of recovery often relies on time and aggressive supportive care. More guidance on supportive treatment of acute toxic hepatopathy is provided in Box 38-4.

Acetaminophen is one of the few toxins with a specific antidote. Acetaminophen is particularly toxic to cats, in which the usual hepatic detoxification pathways of sulphation and glucuronidation are particularly limited. Acetaminophen is oxidized to a toxic metabolite that causes methemoglobinuria within hours of ingestion and Heinz body anemia, hemolysis, and liver failure within 2 to 7 days of ingestion. N-acetylcysteine is a specific antidote that binds the toxic metabolite and increases the glucuronidation process. It should be administered at a dose of 140 mg/kg intravenously or orally as a loading dose and then continued at 70 mg/kg q6h for a total of seven treatments or for up to 5 days. There is also evidence that additional S-adenosylmethionine (20 mg/kg or 200 to 400 mg total daily) is beneficial in cats with acetaminophen toxicity because it replenishes glutathione, which inactivates the toxic metabolite (Webb et al., 2003).

# HEPATOBILIARY INVOLVEMENT IN CATS WITH SYSTEMIC DISEASE

Several feline systemic illnesses have hepatic manifestations that may be identified by physical, clinicopathologic, or radiographic examination, but the major clinical signs can be attributed to another disease (see Table 37-1). In such cases the hepatic lesion should recede with satisfactory treatment of the primary illness.

Metastatic neoplasia could be the underlying reason for abdominal enlargement resulting from hepatomegaly or, rarely, malignant abdominal effusion, although primary neoplasia is more common than metastatic neoplasia in the feline liver. Some of the signs of hyperthyroidism, especially occasional vomiting, diarrhea, and weight loss, can resemble those of primary hepatobiliary disease. Thyrotoxic cats commonly have high liver enzyme activities; more than 75% of affected cats have high serum AP activity (twofold to twelvefold), although in cats it is not known whether this is of liver or bone origin or, as is true for hyperthyroid human patients, both. More than 50% of hyperthyroid cats have high serum ALT or AST activity (twofold to tenfold). More than 90% of affected cats have high serum activity of at least one of the enzymes AP, ALT, and AST. Approximately 3% are hyperbilirubinemic. Histopathologic changes are minimal, and there appears to be little functional disturbance. It is thought that malnutrition, hepatocellular hypoxia, and the direct effects of thyroid hormone on liver cells are responsible for these liver-related abnormalities. Hepatomegaly associated with mild to moderate lipid deposition is a common physical examination finding in cats with diabetes mellitus; a small number of cats may also be icteric. Mild to moderate increases in liver-specific enzyme activities are typical. More severe clinicopathologic abnormalities might be expected in cats with more severe hepatic lipidosis. Hyperadrenocortism is rare in cats, and, unlike in dogs, obvious liver involvement is unusual. The liver is usually normal in size on radiographs, and it is unusual to identify high serum AP and ALT activities in hyperadrenocorticoid cats. Unlike dogs, cats do not possess a steroid-induced isoenzyme of ALP, and increased ALT, when recognized, is probably related to intercurrent diabetes mellitus.

### **GENERAL CONSIDERATIONS**

There are marked differences between dogs and cats in the causes, types, and presentations of liver disease (see Table 37-2). In dogs chronic liver disease is more common than acute disease, and notably, chronic parenchymal disease (chronic hepatitis) is much more common in dogs than cats;

it almost invariably leads to progressive fibrosis and cirrhosis. This contrasts with cats, in which primary biliary disease is more common and fibrosis and cirrhosis extremely uncommon. The clinical signs of liver disease in dogs therefore tend to be even more nonspecific than in cats—jaundice is less common in association with parenchymal disease, and, because of the enormous reserve capacity of the liver, signs may not be seen until 75% of the liver mass is lost. The cause of chronic hepatitis in dogs is usually unknown, with a few notable exceptions, and treatment focuses on attempting to slow progression of disease and treating the clinical signs. Dogs with chronic hepatitis often develop portal hypertension, and treatment of the associated complications are central to treatment of disease in dogs (see also Chapter 39), whereas portal hypertension is very uncommon in cats. Congenital portosystemic shunts (PSSs) are more commonly recognized in dogs than in cats; in addition, vacuolar and secondary hepatopathies are very common in dogs and can be confused with primary liver disease on presentation. The most common primary and secondary liver diseases in dogs are outlined in Table 38-1.

## **CHRONIC HEPATITIS**

Chronic hepatitis is predominantly a histological definition. It is defined by the World Small Animal Veterinary Association (WSAVA) Liver Standardization group as being characterized by hepatocellular apoptosis or necrosis, a variable mononuclear or mixed inflammatory cell infiltrate, regeneration, and fibrosis (Van Den Ingh et al., 2006; Fig. 38-1). The histological definition says nothing about temporal chronicity, and some authors have suggested that increases in liver enzyme activities for more than 4 months associated with inflammatory liver disease might constitute a definite diagnosis of "chronic" hepatitis in dogs.

Chronic hepatitis is common in dogs and shows some noticeable breed predilections, suggesting a genetic basis to the disease. Box 38-1 lists dog breeds reported to have a high prevalence of chronic hepatitis, and Box 38-2 lists possible reasons for genetic increases in susceptibility, all of which

have been demonstrated in humans with chronic hepatitis and some of which have been recognized in other diseases in dogs. Young to middle-aged dogs are most commonly affected, and the sex ratio varies among breeds. It should also be noted that there are some notable geographical differences in breed-related liver diseases, which likely reflect differences in breeding in different countries: Diseases common in the United States may be unusual in the United Kingdom and vice versa. It is also important to remember that chronic hepatitis can affect mixed breed as well as purebred dogs and that recognition of one cause in a breed does not necessarily

mean that chronic hepatitis in all dogs of that breed are due to the same cause. For example, in many Doberman Pinschers and West Highland White Terriers chronic hepatitis is due to copper accumulation, but in others it is not. In many cases of canine chronic hepatitis, the cause is unknown. This contrasts with the situation in human medicine, wherein most cases of chronic hepatitis are viral and some have defined and often effective treatments that can reverse the disease process. In dogs chronic viral causes have not been convincingly demonstrated, but the histology in some cases is suggestive of this and the search for infectious agents con-

BOX 38-2

## Possible Reasons for Breed-related Liver Disease

- Increased susceptibility to infectious causes of chronic hepatitis and/or chronicity of infection
- Mutation in gene involved in metal storage or excretion
- Mutation in gene involved in other metabolic processes (e.g., protease inhibitor production)
- Increased susceptibility to toxic hepatitis (e.g., impaired detoxification of drugs)
- Susceptibility to autoimmune disease

tinues. Most cases therefore remain a nonspecific diagnosis of "chronic hepatitis," and the treatment remains nonspecific and symptomatic. However, in a few notable exceptions, such as copper storage disease and toxic hepatitis, the cause may be known and may be treated specifically. These are outlined in separate sections of this chapter.

#### IDIOPATHIC CHRONIC HEPATITIS

### **Etiology and Pathogenesis**

Idiopathic chronic hepatitis likely represents an unidentified viral, bacterial, or other infection; an unidentified previous toxic event; or, in some cases, autoimmune disease. However, because autoimmune chronic hepatitis has not yet been convincingly demonstrated in dogs, immunosuppressive drugs should not be used or used only very cautiously.

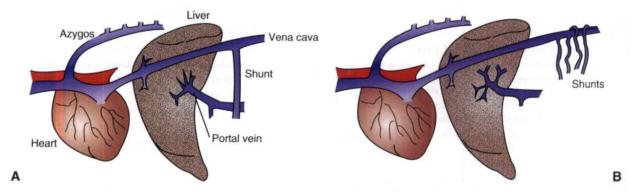

The pathogenesis of chronic hepatitis relates to loss of hepatic mass resulting in loss of function and, late in the disease process, development of portal hypertension. In many cases hepatocyte swelling, fibrosis, and portal hypertension also contribute to cholestasis and jaundice. Ongoing inflammation may also result in bouts of pyrexia and hepatic pain with associated gastrointestinal (GI) and other signs, and many dogs with chronic hepatitis develop negative nitrogen balance and protein-calorie malnutrition. Loss of hepatic function accounts for coagulopathies and adverse drug reactions in affected dogs.

Portal hypertension is an important consequence of chronic hepatitis and fibrosis, and its effects contribute to the clinical signs and death of many affected animals (see also Chapter 39). It causes a typical triad of clinical signs of ascites, GI ulceration, and hepatic encephalopathy (HE). In a healthy dog the pressure in the portal vein is lower than the pressure in the caudal vena cava. However, in association with obstruction and disruption of sinusoids by fibrosis and hepatocyte swelling, portal pressure rises until it exceeds that in the caudal vena cava (portal hypertension). This results in splanchic congestion with splenic congestion, gut wall edema, and eventually ascites. The mechanisms of ascites formation in dogs with liver disease are complex but involve activation of the renin-angiotensin-aldosterone system (RAAS) with sodium retention in the kidneys and increased circulating fluid volume.

If the rise in portal pressure is sustained, multiple acquired PSSs will develop by the opening up of previously nonfunctional vessels; this allows for some of the portal blood to bypass the liver and enter the portal vein directly (Fig. 38-2). These acquired PSSs differ from congenital PSSs in that they are multiple and exist in the presence of increased portal pressure, whereas in patients with congenital PSSs the portal pressure is low. Acquired PSSs lead to HE by a similar mechanism to congenital PSS (see Chapter 39). However, the HE must be medically managed because ligation of acquired PSSs is contraindicated. This is because acquired PSSs are important escape valves to allow dissipation of some of the portal hypertension; therefore any attempt to ligate them will result in fatal splanchic congestion. Acquired PSSs in humans are also recognized to reduce the risk of serious GI ulceration associated with portal hypertension; because of this, they are sometimes created surgically in humans with cirrhosis to reduce the risk of serious bleeds. The same is likely to be true in dogs: GI ulceration is one of the most common causes of death in dogs with chronic hepatitis; acquired PSSs will help reduce this risk.

## **Clinical Features**

Dogs of any age or breed can be affected with idiopathic chronic hepatitis, but there is an increased suspicion in middle-aged dogs of the breeds outlined in Box 38-1. The functional and structural reserve capacity of the liver implies that dogs with chronic hepatitis usually have no clinical signs until late in the disease process, when more than 75% of liver function has gone. By this stage, there is already extensive destruction of liver mass and treatment will be less effective than it would have been earlier in the disease (Fig. 38-3). It is therefore beneficial to diagnose the disease earlier, and dogs with persistently high liver enzyme activities (particularly hepatocellular enzymes such as ALT) should not be

**FIG 38-2**Diagramatic representation of congenital and acquired portosystemic shunts. **A,** Congenital portocaval shunt. **B,** Multiple acquired shunts develop only if the pressure in the portal vein is higher than the pressure in the vena cava.

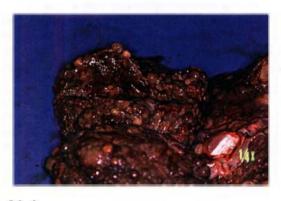

FIG 38-3
Liver from a 6-year-old Bearded Collie that had shown clinical signs for only 1 month before dying from end-stage liver disease. The diagnosis was chronic hepatitis with macronodular cirrhosis and very little normal liver tissue remaining.

ignored. If liver enzyme activities are high for several months and other causes have been ruled out (see the section on secondary hepatopathy), then a liver biopsy should be obtained. This is even more important in breeds at high risk and in those predisposed to treatable diseases, such as copper storage disease.

Once dogs have lost a significant amount of liver mass, they will display clinical signs, but these are typically low-grade, waxing and waning, and nonspecific, making differential diagnosis from other diseases a challenge. Vomiting and diarrhea, anorexia, and polydipsia/polyuria are common. Jaundice and ascites occur in some dogs at presentation and develop later in others, but not in all cases. Ascites at presentation has been identified as a poor prognostic indicator in humans and dogs because it may represent more advanced disease with secondary portal hypertension. HE is uncommon and usually seen only in end-stage disease. The presence of HE strongly suggests the development of acquired PSS. Dogs with chronic hepatitis usually have some degree of protein-calorie malnutrition as a result of chronic hepatic functional impairment and concurrent GI signs. They are

often overtly thin. They may be depressed, but they are also often surprisingly alert considering the severity of their disease.

## **Diagnosis**

Ultimately, a definitive diagnosis requires a liver biopsy, but suspicion of disease is gained from the clinical signs and clinicopathologic features. Clinical signs, clinicopathologic findings, and imaging may be supportive of chronic hepatitis but are not specific. A serum biochemical profile may show a combination of high activities of hepatocellular (alanine transaminase [ALT] and aspartate aminotransferase [AST]) and cholestatic (alkaline phosphatase [ALP] and -glutamyltransferase [GGT]) enzymes, and evidence of decreased parenchymal liver function (low urea, low albumin, and sometimes high bilirubin and bile acid concentrations). Persistent increases in ALT are the most consistent finding in dogs with chronic hepatitis, but they can also be found in other primary and secondary hepatopathies. A high ALP activity is much less specific in dogs, particularly because there is a steroid-induced isoenzyme. Hepatocellular enzymes can become normal in end-stage disease because of a lack of liver mass, but by that stage function tests (e.g., ammonia and bile acid concentrations) will be abnormal, and the dog may even be jaundiced.

Radiographic findings are nonspecific. Dogs with chronic hepatitis often have a small liver (contrasting with cats, in which hepatomegaly is more common), but there is an overlap with normal, and the assessment of liver size is further confused by the variation in gastric axis in deep-chested dogs. If ascites is present, radiographs are not helpful because the fluid obscures all abdominal detail. Ultrasonography is much more useful in assessing hepatic architecture (see Chapter 36). Dogs with chronic hepatitis often have a small, diffusely hyperechoic liver on ultrasonography, although the liver may look ultrasonographically normal in some cases. In other cases it may appear nodular because of macronodular cirrhosis and/or concurrent benign nodular hyperplasia. It is impossible to definitively differentiate benign from malignant nodules on ultrasonographic appear-

ance alone; cytology or biopsy is essential to obtain a definitive diagnosis.

End-stage chronic hepatitis with cirrhosis may appear very similar to noncirrhotic portal hypertension from a diagnostic standpoint, and yet the treatment of the latter is very different and the long-term prognosis much more favorable than with cirrhosis. Therefore a liver biopsy is necessary for a definitive diagnosis and appropriate treatment. It is important to perform a hemostasis profile (one stage prothrombin time; activated partial thromboplastin time, and platelet count) before obtaining a biopsy and to address any coagulopathies or thrombocytopenia before the procedure. Fine needle aspirate (FNA) cytology is of limited value in the diagnosis of chronic hepatitis; the most representative biopsies are wedge biopsies obtained during laparotomy or laparoscopy, although ultrasonographically guided Tru-Cut needle biopsies can be of some benefit.

#### **Treatment**

The aims of treatment of dogs with chronic hepatitis are to treat any identified underlying cause (see subsequent sections), slow progression of the disease if possible, and support liver function and the animal's nutritional and metabolic needs.

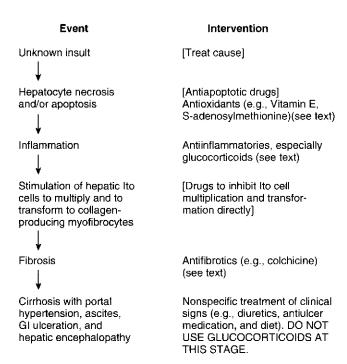

#### Diet

Dietary management is always an important part of treatment in patients with liver disease because the liver is the "first stop" for nutrients on their way from the gut to the systemic circulation and it is intimately involved in the metabolism of nutrients. This metabolism is compromised in patients with liver disease; in addition, dogs with chronic hepatitis typically have protein-calorie malnutrition, so excessive restriction of nutrients can be harmful. The nutritional requirements in dogs with liver disease are outlined in Table 38-2. The most important consideration is dietary protein concentration. It is now recognized in both people and dogs with liver disease that, in order to avoid negative nitrogen balance, dietary protein should not be restricted. However, it is important to feed a high-quality, highly digestible protein to reduce hepatic work and to decrease the amount of undigested protein that reaches the colon, where it is converted to ammonia. Most ammonia reaching the systemic circulation in the portal blood of animals with congenital and acquired PSSs originates not from dietary protein but from enterocyte catabolism of glutamine as their main source of energy. This cannot be avoided without starving the enterocytes, so other means of control of HE are recommended in addition to dietary restriction. Clinical diets available for dogs with liver disease (Hills LD and Royal Canin-Waltham Hepatic support) are ideally formulated, except that they have lower protein than is ideal for a dog with chronic hepatitis. Therefore these diets should be fed as a baseline little and often, with the addition of high-quality protein to the food. Dairy and vegetable protein produce the best results in humans and dogs with liver disease; cottage cheese is a good choice to add to the diet. The amount to add to the food is difficult to estimate. It is advisable to start with 1 or 2 tablespoons of cottage cheese per meal, monitor clinical signs and blood protein levels, and adjust accordingly.

#### Drugs

Drug support in dogs with idiopathic chronic hepatitis is nonspecific and attempts to slow progression of disease and control clinical signs. Specific drug treatments are reserved for patients with an identified underlying cause. Without a biopsy, nonspecific treatment should consist of choleretics, antioxidants, and diet. The use of glucocorticoids must be reserved for biopsy-confirmed cases only.

Glucocorticoids. Glucocorticoids are commonly used in dogs with idiopathic chronic hepatitis, but they should never be used without a biopsy. Biopsies are necessary not only to confirm the presumptive diagnosis but also to rule out any contraindications. There is currently no evidence that idiopathic chronic hepatitis is an autoimmune disease, so glucocorticoids are used in this context for their antiinflammatory and antifibrotic role rather than as immunosuppressives. Fibrous tissue is laid down in the liver by transformed Ito (stellate) cells, and in dogs these are usually stimulated indirectly by cytokines produced by inflammatory cells to transform to collagen-producing cells. The chain of events in idiopathic chronic hepatitis is therefore usually as outlined in Fig. 38-4. Glucocorticoids have an important role to play early in the disease process: Their antiinflammatory effect reduces cytokine formation and Ito

**TABLE 38-2** 

## Dietary Considerations for Dogs with Liver Disease

The diet should be fed little and often (4-6 times a day) and needs to be palatable. A good and sufficient diet is essential for hepatic regeneration and optimal hepatic function.

DIETARY COMPONENT	RECOMMENDATIONS
Protein	Normal amount of high quality (all essential amino acids in optimal amounts), highly digestible (so none left in colon for bacteria to break down to ammonia), and not in excess or requires hepatic metabolism resulting in increased blood ammonia.  Low levels of aromatic amino acids and high levels of branched chain amino acids said to be helpful to reduce hepatic encephalopathy, but evidence is lacking.  Ideal protein to use is dairy or vegetable. Cottage cheese is often used, but it is relatively low in arginine. The easiest way to feed sufficient high-quality protein is to feed a proprietary diet for canine intestinal or liver disease and adjust the protein level to individual's clinical signs. Note diets for canine liver disease have slightly reduced protein content so may need to add more protein e.g., cottage cheese if body weight or blood albumin drops.  Single protein source diet based on dairy or soy protein is recommended after recovery from acute hepatitis.
Fat	No special advice in liver disease. Should not be excessively restricted as an important source of calories and fat maldigestion and steatorrhea because of cholestasis and lack of bile salts very rare. Restrict only if clinical steatorrhea develops. Avoid very high fat diets, particularly with cholestasis or portal hypertension, in which gastrointestinal signs may be exacerbated. Optimizing omega 3: Omega 6 may help reduce inflammation (more research necessary).
Carbohydrate	The carbohydrate used should be highly digestible as a calorie source, reducing need for hepatic gluconeogenesis from fat and protein. Carbohydrate metabolism usually disrupted in hepatic disease. Therefore complex carbohydrates will be better used as an energy source by the animal with liver disease than glucose.
Fiber	Fermentable fiber: may reduce hepatic encephalopathy (conflicting evidence in humans, little evidence in dogs). Broken down to short chain fatty acids in the colon which trap ammonia as ammonium ions. Also beneficial effect on colonic bacteria, increasing nitrogen incorporation into bacteria and reducing ammonia production. (Lactulose is a fermentable fiber).  Nonfermentable fiber: also important because prevents constipation, which is a potential predisposing factor for development of encephalopathy; it increases the contact time for colonic bacteria to act on feces and produce ammonia.  Mixed fiber source in moderate amounts is therefore useful but not too much or it interferes with
Minerals: zinc	the digestion and absorption of nutrients.  Zinc deficiency is common in humans with chronic liver disease. Dogs are proposed to be similar to humans (but little direct evidence exists). Supplementation with zinc proposed to reduce encephalopathy because it is used in metalloenzymes in the urea cycle and in muscle metabolism of ammonia. Zinc is also indicated in copper storage disease because it reduces copper absorption from gut and copper availability in the liver. It may also reduce collagen lay-down in liver and stabilize lysosomal enzymes and also has some antioxidant activity. Supplementing zinc is therefore recommended in any chronic hepatitis in dogs or cats.
Minerals: copper Vitamins: fat soluble	Animals with copper storage disease should be maintained on a low-copper, high-zinc diet.  Vitamin E supplementation may be cytoprotective especially in copper toxicity because of its antioxidant effect.  Vitamin K supplementation may be necessary if clotting times are prolonged, especially if considering biopsies.  Vitamins A and D should not be supplemented. Vitamin A can cause hepatic damage, and
Vitamins: water soluble	vitamin D supplementation can cause calcification in tissues.  B vitamins should be supplemented because there is increased loss in polydipsia/polyuria associated with liver disease. It is recommended that dogs with liver disease receive a double dose of B-vitamins.  Vitamin C should not be supplemented because ascorbate can increase the tissue damage associated with copper and iron in liver disease.

cell stimulation, thus reducing fibrous tissue deposition. They are therefore indicated early in the disease process, when there is inflammation and minimal fibrosis, and once infectious etiologies have been ruled out. In these situations they may slow the progression of the disease (although that has not been proved). The logical dose to use is antiinflammatory (equivalent to 0.5 mg/kg of prednisone and gradually reducing over several weeks by halving the dose and reducing to every-other-day treatment), although immunosuppressive doses also have been used; there is currently insufficient evidence in dogs to advise which is correct.

Glucocorticoids are contraindicated later in the disease, when there is portal hypertension and end-stage fibrosis, or in conditions with noninflammatory fibrosis (e.g., noncirrhotic portal hypertension), in which there is no reason for their use. In these circumstances they are also likely to shorten the life expectancy by increasing the risk of serious GI ulceration (see Fig. 39-1). Hence glucocorticoids should never be used without a histopathologic diagnosis and staging of disease.

Other antiinflammatory or immunosuppressive drugs. Some of the other drugs used in dogs with liver disease also have antiinflammatory activity, particularly zinc, S-adenosylmethionine, and ursodiol (discussed in more detail later). Azathioprine has occasionally been used in dogs with chronic hepatitis, but there is no evidence that it is beneficial; until immune-mediated causes of chronic hepatitis have been proved, it would be wise to avoid the use of this or other potent immunosuppressive medications.

Choleretics. Ursodiol is widely and commonly used in dogs with chronic hepatitis. It is a synthetic hydrophilic bile acid that is choleretic and also modulates the bile acid pool in biliary stasis, making the bile less toxic to hepatocytes. It also has antiinflammatory and antioxidant properties, and recent studies suggest that it is synergistic with S-adenosylmethionine and vitamin E. The only absolute contraindication is complete biliary obstruction, which is very rare in dogs and would usually result in obvious acholic feces. It is logical to use it in any dog with chronic hepatitis, particularly in those associated with biliary stasis, and it can safely be used without a biopsy. However, as with other drugs used in canine liver disease, there is very limited (although encouraging) evidence as to its efficacy. It may be more helpful in some diseases than others, but this is not known yet in dogs. The recommended dose is 10 to 15 mg/kg q12h (or split into two doses given q12h).

Antioxidants. A variety of antioxidants are used in dogs with chronic hepatitis. The most well-documented are vitamin E and S-adenosylmethionine. Vitamin E appears to be beneficial at a dose rate of 400 IU/day for a 30-kg dog given as a water-soluble preparation once a day. Doses for smaller dogs are scaled appropriately. S-Adenosylmethionine is a glutathione precursor and is of particular benefit in dogs with toxic hepatopathy (discussed in more detail later) and those with biliary stasis because bile is a potent oxidant. It is synergistic with Vitamin E and ursodiol, and an argument could be made for it being beneficial in any dog with

chronic hepatitis. The recommended dose is 20 mg/kg PO q24h. There are some studies documenting its use in dogs, but more are needed to define in which diseases it is most useful. S-Adenosylmethionine is a very unstable molecule (because it is a methyl donor) and must therefore be carefully packaged and given on an empty stomach. The pharmokinetics and GI availability in dogs are known for the pure preparation (Denosyl SD4; Nutramax Laboratories), but it is increasingly being marketed as a polypharmacy nutraceutical in preparations with other nutraceuticals and vitamins mixed together. Pharmacokinetic and absorption data should be sought from the manufacturers of these products to ensure that the S-adenosylmethionine is absorbed in effective amounts.

Another antioxidant commonly used in dogs with chronic hepatitis is milk thistle (Silybum marianum). The active ingredients are flavonoids, commonly referred to as silymarin, and the most effective of these is believed to be silybin. There are very few studies of the use of flavonoids in dogs, and the only clinical studies are on acute toxic hepatitis. Silybin undoubtedly has the potential to be a helpful adjunct to therapy in some cases, but much more information on absorption, availability, and ideal dosage is necessary. Silybin is included in many nutraceuticals marketed for dogs with liver disease. One recent study (Filburn et al., 2007) showed that it had very poor absorption alone but was much more bioavailable when complexed with phosphatidylcholine.

Therefore, although antioxidant nutraceuticals have great potential benefits in the treatment of chronic liver disease in dogs and can be safely used without a biopsy, the clinician must be aware of the emerging nature of the information about their bioavailability and efficacy and choose products carefully with this in mind.

Antifibrotics. In inflammatory liver disease and early fibrosis, glucocorticoids have a potent indirect antifibrotic activity by reducing inflammation, as outlined in the preceding sections. Later in the disease process, when there is extensive fibrosis, the direct antifibrotic agent colchicine can be used; there is limited but encouraging anecdotal evidence supporting its effectiveness in dogs. It is an alkaloid derivative that binds tubulin and has the potential to reverse fibrosis. The recommended dose in dogs is 0.03 mg/kg/day PO. Adverse effects are uncommon in dogs but include bone marrow suppression and anorexia/diarrhea; it is the latter that often limits its use in clinical cases.

Antibiotics. There is a primary indication for the use of antibiotics in dogs with ascending biliary tract infections or suspected bacterial infection as a cause of the chronic hepatitis. The latter is rarely proved, but if it is possible that atypical leptospiral infection may be present (e.g., if chronic hepatitis is seen in a dog with access to sources of infection such as rivers or ditches), a course of appropriate antibiotics would be wise to rule this out. The recommended therapy for leptospiral infections is to start with intravenous (IV) amoxicillin at a dose of 22 mg/kg q12h to terminate replication and reduce potentially fatal liver and kidney complications. If leptospiral infection is subsequently confirmed (on

rising titres on serology, dark field microscopy, or PCR of the urine for organisms), this should be followed by doxycycline therapy (5 mg/kg PO q12h for 3 weeks) once liver function is normal to eliminate the chronic renal carrier state. *Bartonella* spp. have occasionally been associated with chronic liver disease in dogs. The optimal treatment for *Bartonella* spp. in dogs has not been established. Macrolides (e.g., erythromycin) or alternatively fluoroquinolones or doxycycline have been shown to have some efficacy against some *Bartonella* spp. in dogs. It has been suggested that 4 to 6 weeks of treatment might be necessary to eliminate infection.

Antibiotics are also used as part of supportive treatment in dogs with HE caused by acquired PSS in end-stage chronic hepatitis, in a similar way to dogs with congenital PSS to reduce toxin absorption from the gut and the risk of systemic infections (see Chapter 39). Ampicillin is often used long term in these cases at a dose of 10 to 20 mg/kg, PO or IV q8-12h.

As with other drugs, the clinician should avoid any antibiotics that increase hepatic work or the risk of hepatotoxicity. Thus tetracyclines, potentiated sulphonamides, nitrofurantoin, and erythromycin should be avoided unless necessary (e.g., with confirmed leptospirosis or bartonellosis) because they are potentially hepatotoxic.

### COPPER STORAGE DISEASE

### Pathogenesis and Etiology

Copper storage disease has been recognized as a cause of acute and chronic hepatitis in several breeds, the best researched of which is the Bedlington Terrier (see Box 38-1). Other breeds in which copper storage disease has been reported are Dalmatians (in the United States and Canada), Labrador Retrievers (in the United States and Holland), and some Doberman Pinschers (in Holland), although individual members of all these breeds have also been reported with chronic hepatitis without copper accumulation. In addition, copper storage disease has been suspected but not extensively investigated in West Highland White Terriers and Skye Terriers. It is also possible for seemingly normal dogs without a recognized copper storage disease to develop copper-associated chronic hepatitis if fed a diet very high in copper, such as dry calf feed (Van den Ingh et al., 2007).

Copper is excreted in the bile and can build up as a secondary phenomenon in any type of chronic hepatitis associated with cholestasis. In these cases the accumulation is usually mild, often in zone 1 (peribiliary), and the amount of copper does not correlate with the severity of the disease. It is unclear whether copper chelation is helpful in dogs with secondary copper build-up, but probably it is not. The peribiliary distribution and lack of correlation between amount of copper build up and clinical signs helps to distinguish these cases from "true" copper storage disease, in which the copper accumulation is the cause rather than an epiphenomenon of the disease and accumulation is usually marked, progressive, correlated with disease severity, and in

Zone 3 (perivenous; see Fig. 35-4 for an explanation of hepatic zonation).

True copper storage disease likely represents a genetic defect in copper transport and/or storage, but the only breed in which this has been defined is the Bedlington Terrier. In this breed it is inherited as an autosomal recessive trait, and up to 60% of Bedlington Terriers in some countries have been affected in the past, although the prevalence is now decreasing as a result of selective breeding. The disease is confined to the liver, and there appears to be a specific defect in hepatic biliary copper excretion (probably in transport from the hepatocyte lysosomes to the biliary tract). Recent work has identified at least one genetic defect associated with the disease: a deletion in the MURR1 gene (now COMMD1; Van de Sluis et al., 2002), which codes for a protein of unknown function. However, Bedlington Terriers with copper storage disease but without a COMMD1 deletion are now being reported in the United States, United Kingdom, and Australia (Coronado et al., 2003; Heywood, 2006; Hyun et al., 2004), suggesting that there is at least one other mutation involved in the breed that has yet to be identified.

#### **Clinical Features**

Affected Bedlington Terriers can present with either acute or chronic clinical signs, depending on individual factors, such as the amount of copper in the diet, and also likely other factors, including concurrent stress and disease. If there is rapid and marked build-up, dogs may present with acute fulminant hepatic necrosis and no previous clinical signs. This is usually seen in young to middle-aged dogs and is often accompanied by acute hemolytic anemia caused by the rapid release of copper into the circulation. The prognosis is poor, and most animals die within a few days. Fortunately, this is uncommon; most dogs have a more chronic, protracted course with several years of copper build-up and persistently high ALT activity, culminating in the development of chronic hepatitis with piecemeal necrosis, inflammation, and bridging fibrosis. Clinical signs are therefore recognized in these individuals only late in the disease process and are usually those of canine chronic hepatitis. These dogs usually present at about 4 years old but may be younger (Fig. 38-5). Eventually, if not treated, affected dogs will develop cirrhosis.

The clinical signs and progression in other breeds with copper storage disease are similar to those in Bedlington Terriers. The disease in Dalmatians is associated with acute onset, rapid progression, and very high levels of hepatic copper in the absence of significant clinical, clinicopathological, or histological evidence of cholestasis. Affected dogs usually present as young adults with acute onset of GI signs and polydipsia/polyuria, by which time severe liver disease is already present. Labrador Retrievers with copper storage disease have an average age at presentation of 7 to 9 years (range, 2.5 to 14 years). The clinical signs are relatively mild and included anorexia, vomiting, and lethargy. Doberman Pinschers appear to have a long phase of subclinical disease culminating, in untreated cases, in an acute-on-chronic

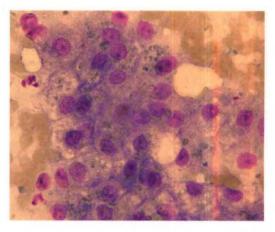

FIG 38-5
Beddlington Terrier with copper storage disease. (From Hall EJ, Simpson JW, Williams DA, editors: BSAVA manual of canine and feline gastroenterology, ed 2, Gloucestershire, United Kingdom, 2005, British Small Animal Veterinary Association.)

disease and rapidly progressive deterioration. However, it is unclear how many of the clinically affected Doberman Pinschers described in the literature had copper storage disease and how many had idiopathic chronic hepatitis, so the true presenting signs of copper storage disease in this breed are unclear. Most published studies on true copper storage disease in Doberman Pinschers describe diagnosis and treatment of subclinical disease.

### **Diagnosis**

The magnitude of increase in liver enzyme activities and the diagnostic imaging findings in dogs with chronic copper storage disease are very similar to those of dogs with idiopathic chronic hepatitis. Therefore a definitive diagnosis requires a liver biopsy and estimation of the copper concentration in the liver. This can be done qualitatively on formalin fixed sections using rhodanine staining to detect copper; correlations between quantitative and qualitative estimation of copper accumulation have been published (Shih et al., 2007). The finding of large accumulations of copper in hepatocytes on cytology with rubeanic acid is also very suggestive of copper storage disease (Fig. 38-6; Teske et al., 1992). Quantitative measurement of copper content can also be performed, but this requires a large biopsy specimen carefully taken and stored in copper-free tubes. In addition to estimating copper content, the liver biopsy will give an indication of the chronicity and extent of liver damage, which will affect treatment decisions in a very similar way to chronic hepatitis. Bedlington Terriers can be tested for the COMMD1 deletion either before breeding or when newly acquired to assess their risk for this disease, but an absence of the COMMD1 deletion does not guarantee that the dog will not be affected. The genetic test is currently offered via mouth swabs at the Animal Health Trust in Newmarket, U.K. (details at http://www.aht.org.uk/sci\_diag\_disc\_genetic\_main.htm) and by Vet Gen in the United States (www.vetgen.com). To rule out copper storage disease through a liver biopsy in a

Cytology of hepatocytes from Bedlington terrier with copper storage disease demonstrating copper granules (rubeanic acid stain). (Courtesy Elizabeth Villiers; from Hall EJ, Simpson JW, Williams DA, editors: BSAVA manual of canine and feline gastroenterology, ed 2, Gloucestershire, United Kingdom, 2005, British Small Animal Veterinary Association.)

breeding animal, clinicians should obtain a biopsy when the dog is about 12 months old, by which time there will be sufficient copper build-up to diagnose the disease. In much older animals, cirrhosis with nodular regeneration can develop, and the nodules will have a lower copper content than the rest of the liver, confusing diagnosis if a regenerative nodule is inadvertently biopsied.

#### **Treatment**

The ideal treatment in a dog known to be affected is prevention. Bedlington Terriers with the COMMD1 mutation should be fed a low-copper, high-zinc diet. The proprietary liver diets formulated for dogs (Royal-Canin Hepatic support or Hills canine LD) have low copper and high zinc concentrations but are also moderately protein restricted, so it would be wise to supplement with a low-copper protein source (e.g., cottage cheese) in growing dogs. It is also important to avoid giving the dog tap water from copper pipes in soft water areas; bottled water should be used instead. Box 38-3 gives a list of common high-copper foods that should be avoided and high-zinc foods that could be supplemented.

Dogs that present with an acute crisis should be treated with intensive support in exactly the same way as dogs with acute hepatitis (Box 38-4). Blood transfusion may be necessary if hemolysis is severe. Copper chelation is unlikely to be beneficial acutely, but chelation with 2,2,2-tetramine (trientine) could be considered (or 2,3,2-tetramine if obtainable) because this can chelate rapidly. Trientine is available as a drug licensed for humans (Syprine,® Merck Sharp and Dohme). The recommended dose in dogs is 10 to 15 mg/kg PO q12h 30 minutes before a meal. 2,3,2-Tetramine is difficult to obtain. Penicillamine is *not* helpful in an acute crisis because chelation takes weeks to months. However, it should be noted that there is much less information available about

BOX 38-3

Foods Rich in Copper and Zinc

#### Copper

- \*Shellfish
- \*Liver
- Kidney, heart
- Cereals
- Cocoa

- Liver
- Whole grains, lentils
- Rice
- Potatoes

the pharmacokinetics, drug interactions, and toxicity of trientine in dogs than there is for D-penicillamine. Reported adverse effects include nausea, gastritis, abdominal pain, melena, and weakness. On recovery, the animal should continue on long-term treatment, as outlined in the following sections.

Treatment of dogs that already have high hepatic copper concentrations documented by biopsy but are not in an acute crisis consists of active copper chelation, zinc supplementation, and use of a low-copper diet and additional supportive therapy. The chronic hepatitis secondary to copper storage disease should be treated the same way as in dogs with idiopathic chronic hepatitis, using antioxidants, ursodiol, and other supportive medication (see the section on chronic idiopathic hepatitis). There is a particular role for antioxidants such as vitamin E and S-adenosylmethionine in metal-induced liver injury. Chelation can be achieved using either D-penicillamine or trientine. D-penicillamine takes months to have a significant effect on the copper content of the liver but is easily available and its pharmacokinetics and toxicity in dogs are well documented. The recommended dose is 10 to 15 mg/kg PO q12h 30 minutes before meals. It also has weak antifibrotic and antiinflammatory properties. Starting at the lower end of the dose range and increasing the dose after 1 week (or dividing the dose and giving it more frequently) can reduce the common adverse effects of vomiting and anorexia. It has also been reported to cause nephrotic syndrome, leukopenia, and thrombocytopenia in dogs, so a complete blood count and urine samples should be monitored regularly during therapy. A decrease in liver copper content of about 900 µg/g dry weight per year can be anticipated in dogs treated with D-penicillamine. Trientine (2,2,2 tetramine) is another efficacious copper chelator that

# Outline of Treatment Recommendations for Acute Fulminant Hepatitis

- Identify and treat cause if possible (e.g., remove drugs implicated; treat leptospirosis; give N-acetylcysteine (150 mg/kg by IV infusion in 200 ml 5% glucose over 15 minutes, followed by 50 mg/kg IV infusion in 500 ml over 4 hours then 100 mg/kg IV infusion in 1000 ml over 16 hours) +/- cimetidine (5-10 mg/kg IV, IM or PO tid) for acetaminophen toxicity).
- Fluids: Careful IV fluid therapy: dextrose saline with added potassium often most appropriate. Measure blood glucose and electrolyte concentrations every few hours and adjust appropriately. Use peripheral catheter and monitor renal function (use central catheters only when confirmed that there is no coagulopathy or high risk of unnoticed bleeding around catheter). Monitor carefully: Ensure adequate urine output and reversal of dehydration, but do not overinfuse or worsen fluid retention.
- Treat coagulopathy as necessary: Consider fresh frozen plasma and vitamin K.
- Treat acute hepatic encephalopathy: Consider propofol infusions and lactulose/neomycin enemas. Regularly monitor blood glucose and potassium, and supplement as necessary.
- Treat any gastrointestinal ulceration: Consider acid secretory inhibitors (ranitidine or omeprazole).
- Treat any ascites with spironolactone +/- furosemide (see Chapter 39).
- Consider antibiotics in all cases to protect against infectious complications, particularly septicemia of gut origin.
   Certainly give antibiotics to all pyrexic cases intravenously. Use broad-spectrum agents that are safe in liver disease.
- Food: Nothing by mouth for first 1 to 3 days; then feed diet based on dairy or soy protein: high quality protein, not restricted.

may be used and can remove copper from the liver more rapidly than D-penicillamine. Details of dose and potential adverse effects are given in a preceding section.

Copper chelation treatment is continued until normal liver copper concentration is reached; this is best determined by liver biopsy and copper quantification or cytologic estimate. Treatment should then be stopped to prevent copper deficiency, which can occur after prolonged, overzealous copper chelation and can result in severe effects of copper deficiency with weight loss and hematemesis. The regimen can then be changed to a preventive protocol consisting of a copper-restricted diet and zinc administration.

# INFECTIOUS CAUSES OF CANINE CHRONIC HEPATITIS

Primary chronic hepatitis caused by infectious agents is uncommon in dogs, although there may be a yet unidenti-

particularly high in copper

fied infectious cause in some dogs with what appears to be idiopathic chronic hepatitis. Clinicians should keep this possibility in mind before prescribing immunosuppressive medication.

To date, there has been no convincing demonstration of a viral cause of canine chronic hepatis, although it has been suspected in several cases. The most common viral cause of chronic hepatitis in people is hepatitis B virus, a hepadnavirus. Similar hepadnaviruses associated with hepatitis have been identified in woodchucks, ground squirrels, tree squirrels, and ducks, but attempts to identify hepadnaviruses by PCR in the liver of dogs with chronic hepatitis or hepatocellular carcinoma have failed. Two other viruses have been suggested as a possible cause of canine chronic hepatitis: canine adenovirus type 1 (CAV1) and canine acidophil cell hepatitis virus. CAV1 causes acute fulminant hepatitis in immunologically naive dogs, but it can also cause chronic hepatitis experimentally in partially immune dogs. However, its importance in naturally occurring chronic hepatitis is unclear, and studies are conflicting. An alternative viral cause of canine acute, persistent, and chronic hepatitis was proposed in Glasgow by Jarrett et al. in 1985 and named canine acidophil cell hepatitis virus pending isolation and identification. The virus appeared to be transmissible by subcutaneous injection of liver homogenate and serum and was apparently capable of producing a chronic hepatitis marked by fibrosis and hepatocyte necrosis, but sparse inflammatory changes (Jarrett et al., 1985, 1987). It was proposed at the time that this was the most important cause of hepatitis in Glasgow. However, there have been no further published studies by either these or other workers regarding the identity or significance of this virus, so its identity and role remain unknown.

Bacterial infections have been sporadically reported as a cause of canine chronic hepatitis, but their importance is unclear. Bile-tolerant *Helicobacter* spp. can cause hepatitis centered on the bile ducts in rodents; there is one report of necrotizing hepatitis associated with *Helicobacter canis* infection in a pup (Fox et al., 1996). However, no further work has been reported in dogs, and a clear association between *Helicobacter* infection and liver disease has yet to be demonstrated.

Infections with apparently atypical leptospires may be a clinically relevant and underestimated cause of chronic hepatitis in dogs. Most dogs in the United States are vaccinated regularly against *Leptospira interrogans* serovars *canicola* and *icterohaemorrhagiae*, so it is assumed that leptospiral infection is now a rare disease. However, recent studies have shown an emergence of diseases associated with other serovars; in addition, there is little immunologic cross-reaction with the vaccine serovars. Infection with "atypical" leptospires, particularly *L. grippotyphosa*, can cause a chronic hepatitis with ascites, particularly in young dogs; azotemia is uncommon in these dogs. Histologically, the liver of dogs with confirmed atypical leptospire infection has portal and intralobular inflammation (i.e., mainly lymphocytic-plasmacytic with some neutrophils and macrophages). There

may also be periportal and portoportal fibrosis that may disrupt the hepatic architecture. The organisms are sparse and difficult to find with conventional staining techniques, so it is very possible that some cases of leptospiral hepatitis are misdiagnosed as immune-mediated disease on the basis of the histological appearance. There is also often a poor serological response in affected dogs, further complicating diagnosis.

Adamus et al. (1997) noted the similarity in age bias (6 to 9 months) and histological appearance between leptospiral hepatitis and lobular dissecting hepatitis, and it has been suggested that undiagnosed infections may be a cause of lobular dissecting hepatitis in some young dogs (discussed in more detail later). There have also been recent sporadic reports of *Bartonella henselae* and *Bartonella clarridgeiae* in dogs with chronic liver disease, but again their significance as a cause of the disease is unclear. Peliosis hepatis, rather than chronic hepatitis, is the more classical histological appearance associated with *Bartonella* spp. infection in humans and has been reported in one dog (Kitchell et al., 2000). Serology or PCR for *Bartonella* spp. is available.

A recent study (Boomkens et al., 2005) evaluated 98 liver samples from dogs with chronic hepatitis using nested PCR for Hepadnaviridae, *Helicobacter* spp., *Leptospira* spp., *Borrelia* spp., hepatitis A virus, hepatitis C virus, hepatitis E virus, canine adenovirus, and canine parvovirus and failed to find evidence of infection in any of the dogs. More work is needed before potential infectious causes of chronic hepatitis in dogs can be completely ruled out.

#### LOBULAR DISSECTING HEPATITIS

Lobular dissecting hepatitis is an idiopathic inflammatory disorder recognized predominantly in young dogs; it has a typical histological appearance of fibrotic dissection of lobular parenchyma into individual and small groups of hepatocytes. It has been reported in several breeds, including families of Standard Poodles and Finnish Spitzes. It has been proposed that lobular dissecting hepatitis does not represent a distinctive disease but rather a response of the juvenile liver to a variety of insults. Infectious etiologies have been suggested, although not proved, and the age of onset and histological appearance bear a striking resemblance to atypical leptospiral infection in dogs. Treatment recommendations are similar to those for canine chronic hepatitis (see preceding section).

### TOXIC CAUSES OF CHRONIC HEPATITIS

Toxins and drug reactions more commonly cause acute, necrotizing hepatitis than chronic disease. Phenobarbital or primidone can cause either acute or chronic hepatotoxicity (see later discussion). Lomustine (CCNU) can also cause delayed, cumulative dose-related, chronic hepatotoxicity that is irreversible and can be fatal. Another occasional reported cause of chronic liver damage is phenylbutazone. Most other reported hepatotoxic drugs and toxins cause an acute hepatitis (see section on acute hepatitis and Box 38-5). Certain mycotoxins, including aflatoxins, can cause acute or

chronic liver disease in dogs depending on the dose ingested and period of exposure. Dogs scavenge and eat contaminated food more often than humans do, so it is possible that a number of cases of canine chronic hepatitis are due to acute or chronic ingestion of unidentified toxins. Because a wide variety of drugs have been reported as causing hepatic adverse reactions in humans and dogs, a drug reaction should be considered in any dog with chronic hepatitis that is also on long-term therapy of any sort, although care should be taken not to overdiagnose drug reactions; chronic hepatitis should be considered as possibly drug related only when there is a clear temporal relationship with drug intake and likely alternative causes have been excluded.

### **ACUTE HEPATITIS**

### **Etiology and Pathogenesis**

Acute hepatitis is much less common than chronic hepatitis in dogs but, when severe, carries a much poorer prognosis. Treatment focuses on providing supportive measures and allowing the liver to recover. Dogs with acute hepatitis are at high risk of disseminated intravascular coagulation (DIC). Severe loss of liver function is also fatal because it cannot be replaced artificially while awaiting recovery; there is no such

thing as liver dialysis. However, because of the remarkable regenerative capacity of the liver, animals that recover from the acute phase of the disease can recover completely, with no permanent hepatic injury, as long as they are fed and supported properly.

Most causes of acute fulminating hepatitis in dogs are infectious or toxic (see Box 38-5). In unvaccinated dogs CAV-1 and leptospira are important differential diagnoses. Dogs with copper storage disease can present acutely and often will have hemolysis associated with high serum copper concentration, in addition to acute hepatic necrosis. Xvlitol, an artificial sweetener, has recently been reported to cause acute hepatic necrosis in dogs (Dunayer et al., 2006) with a high mortality. Aflatoxin in contaminated feed-stuffs also recently caused acute and subacute hepatitis with a high mortality in dogs (Newman et al., 2007). The most common drugs implicated in causing acute hepatic necrosis in dogs are listed in Box 38-5, but potentially any drug could cause idiosyncratic hepatic necrosis in an individual dog. Recently, a case of destructive cholangitis ("disappearing bile duct syndrome") was reported in a dog as a suspected drug reaction to either one or a combination of amoxicillinclavulanate, amitraz and milbemycin oxime (Gabriel et al., 2006), and we have seen this in a clinical case likely caused by an indiosyncratic reaction to amoxicillin-clavulanate.

### **Clinical Features**

The clinical features of acute fulminating hepatitis, independent of the cause, relate to the acute loss of hepatic function together with the effects of generalized cell necrosis and release of inflammatory cytokines and tissue factors. Dogs usually present with acute onset of one or more of the following: anorexia; vomiting; polydipsia; dehydration; hepatic encephalopathy with depression progressing to seizures and/or coma; jaundice; fever; cranial abdominal pain; coagulopathy with petechiae and possible hematemesis and melena; and, in some cases, ascites and splenomegaly resulting from acute portal hypertension. Renal failure is a severe complication in some cases with both prerenal and intrinsic renal components. In humans with acute hepatic failure, hypotension, cardiac arrhythmias, cerebral and pulmonary edema, and pancreatic inflammation also have been reported; these may occur in some dogs, although they have not been specifically reported.

### Diagnosis

Diagnosis is usually made on the basis of history, clinical signs, and clinicopathologic findings. Liver histopathology should be confirmatory, but results are often not obtained until recovery (or postmortem) because of the severe acute nature of the disease. A history of recent drug or toxin exposure is important in implicating these as a cause; vaccination status is an important consideration for infectious causes.

On clinical pathology dogs with acute hepatitis often have early, marked increases in hepatocellular enzyme ALT and AST activities (tenfold to >100-fold). Jaundice and increases in markers of cholestasis may also occur; the rare cases of

destructive cholangitis are characterized by early, severe jaundice and marked increases in ALP activity and hyperbilirubinemia. Hypoglycemia and hypokalemia are common in dogs with acute hepatitis, and azotemia is seen in some cases, as a result of both prerenal and renal causes. Hemostatic abnormalities, with both prolonged clotting times and thrombocytopenia, are frequently present and can be a sign of developing DIC (see Chapter 87). Diagnostic imaging is not usually very helpful in dogs with acute hepatitis. There may be hepatomegaly and a diffuse change in hepatic echogenicity; in some cases there may be splenic congestion and/ or ascites, but these changes are not specific and do not help define the cause or extent of the damage. In some patients the ultrasonographic exam is unremarkable.

### Treatment and Prognosis

Treatment of acute fulminant hepatitis in dogs is largely supportive and is outlined in Box 38-4. Every attempt should be made to identify and treat the primary cause at the same time that supportive therapy is instituted. Corticosteroid treatment is not indicated in these cases and may in fact worsen the prognosis by increasing the risk of GI ulceration and thrombosis. The owner should be warned of the poor prognosis for recovery in spite of intensive support, and in severe cases, early referral to an intensive care unit should be considered. However, dogs that recover from the acute phase have a good chance of complete recovery. Some research in humans and animals has suggested that chronic liver lesions are less likely to develop if a single-protein milk or soybean-based diet is fed in the recovery phase.

### **BILIARY TRACT DISORDERS**

Biliary tract disorders are less common in dogs than in cats, but both primary biliary tract disorders and extrahepatic bile duct obstruction are recognized in dogs. In addition, destructive cholangitis caused by drug reactions leading to severe cholestasis and icterus has been recognized occasionally in dogs (but not cats). Dogs occasionally develop congenital hepatic and renal cysts, similar to Caroli's disease in humans.

### **CHOLANGITIS AND CHOLECYSTITIS**

As discussed in the preceding section, primary biliary tract disease is less common in dogs than in cats. The clinical signs and diagnostic evaluation are very similar to those in cats with neutrophilic cholangitis (see Chapter 37). Dogs can be of any age or breed, and the typical presentation is acute onset of anorexia, jaundice, and vomiting, with or without pyrexia. In some cases there may have been a previous history of acute enteritis or pancreatitis, suggesting a potential cause for ascending biliary infection from the gut. Mechanical obstruction and gallbladder mucocele (discussed in more detail later) should be ruled out first, usually by ultrasonography, and then liver and bile and/or gallbladder mucosa specimens should be obtained for histopathology and micro-

bial culture and sensitivity testing, preferably before antibiotic treatment is initiated.

Liver biopsies and bile samples can be obtained by direct visualisation during surgery or laparoscopy or via ultrasonographic guidance. The latter method carries a greater risk of bile leakage; to minimize this, a 22-gauge needle attached to a 12-ml syringe is used for cholecystocentesis (bile retrieval), and an attempt is made to evacuate the gallbladder. The procedure is best performed under general anesthesia rather than heavy sedation to minimize the chance of patient motion during aspiration. The risk of iatrogenic bile or septic peritonitis is greatest with patients with a severely diseased gallbladder wall (determined ultrasonographically); surgical treatment is necessary if bile peritonitis occurs. Enteric organisms similar to those found in cats are most commonly found, and the most common isolate in several studies is Escherichia coli. Other organisms reported are all of gut origin and include Enterococcus sp., Klebsiella sp., Clostridium sp. (which may be a gas-forming species causing emphysematous changes in the gallbladder wall visible radiographically), fecal Streptococcus sp., Corynbacterium spp., and Bacteroides sp. Antibiotic resistance is relatively common among isolates and can also develop during therapy, underscoring the importance of obtaining bile samples for culture and sensitivity whenever possible. Choleliths can be found in association with cholecystitis or cholangitis; the cause-and-effect relationship is not always clear.

#### **GALLBLADDER MUCOCELE**

Gallbladder mucocele has recently been reported as a common cause of clinical signs of biliary tract disease in dogs (Figure 38-7). The cause is unclear, but it is most common in middle-aged to older dogs; there appears to be a breed predisposition in Shetland Sheepdogs in the United States (Aguirre et al., 2007). Other suggested breed associations are Cocker Spaniels and Miniature Schauzers. It has been proposed that sterile or septic inflammation of the gallbladder wall and/or disordered gallbladder motility predispose to mucocele formation. In the Shetland Sheepdogs there appeared to be an association between gallbladder mucocele and dyslipidemias, usually caused by other concurrent diseases such as pancreatitis, hyperadrenocorticism, hypothyroidism, and diabetes mellitus.

Clinical signs vary. In some dogs mucocele is clinically silent and is an incidental finding on abdominal ultrasonography (Fig. 38-7). In others nonspecific clinical signs are seen similar to those of other biliary tract diseases with anorexia, lethargy, vomiting, and icterus. Some dogs present acutely because of gallbladder rupture and bile peritonitis.

Treatment is usually surgical for clinically affected dogs with cholecystectomy with or without biliary diversion. There is a high perioperative mortality, particularly for dogs that have biliary diversion surgery. However, those that survive the perioperative period have a good long-term prognosis. Medical management of subclinical mucoceles has been reported in Shetland Sheepdogs (Aguirre et al., 2007). This consisted of a low-fat diet (such as Hills ID or

Royal-Canin Waltham intestinal low fat or Eukanuba intestinal diets) with a choleretic (ursodeoxycholic acid 10-15 mg/kg total dose daily, preferably split twice daily) and an anti-oxidant (S-adenosylmethionine 20 mg/kg PO q24h). In one dog this resulted in resolution of the mucocele, in two dogs the mucocele remained static, one dog died as a result of gallbladder rupture, and one dog died as a result of pulmonary thromboembolism, both within 2 weeks of diagnosis; two dogs were lost to follow-up. It would seem sensible also to address the underlying cause of the dyslipidemia in all cases, whether surgically or medically managed.

# EXTRAHEPATIC BILE DUCT OBSTRUCTION

The causes of extrahepatic bile duct obstruction (EBDO) in dogs are very similar to those in cats (see Box 37-4) with the exception of liver flukes, which are uncommon in dogs.

The most common cause of EBDO in dogs is extraluminal obstruction from acute-on-chronic pancreatitis (see Chapter 40), but intestinal foreign bodies, neoplasia, bile duct involvement in a diaphragmatic hernia, and other processes can also cause EBDO (Fig. 38-8). Bile duct injuries that heal and result in stricture formation several weeks later are also seen in dogs; the common bile duct (CBD) may be compressed when carried with the liver into the thorax in dogs with diaphragmatic hernia. Extraluminal compressive lesions, such as pancreatic, biliary, or duodenal neoplasms, are less common causes, and cholelithiasis as a cause of EBDO is rare. To be considered EBDO, a pathologic process must exist at the level of the CBD that impedes bile flow into the duodenum. Only if bile flow has been completely interrupted for several weeks do acholic feces, vitamin K-responsive coagulopathy, and repeated absence of urobilinogen in properly processed urine specimens occur. If obstruction is incomplete, these features are not present and the constellation of signs and clinicopathologic test results resembles those of other, nonobstructive biliary tract disorders.

#### **BILE PERITONITIS**

Bile peritonitis results most often from abdominal trauma damaging the common bile duct (e.g., penetrating injury, horse kick, automobile accident) or pathologic rupture of a severely diseased gallbladder, which sometimes occurs after diagnostic ultrasonography-guided aspiration. Early signs of bile peritonitis are nonspecific, but with progression, jaundice, fever, and abdominal effusion are seen. When bile, which is normally sterile, comes in contact with the peritoneal surface, resultant cell necrosis and changes in permeability predispose to infection with bacteria that move across the intestinal wall. Hypovolemia and sepsis may occur in animals with undetected bile peritonitis.

### **Clinical Features**

Presenting clinical signs and clinicopathologic and physical examination findings of all these disorders may not differ greatly unless the underlying condition has caused EBDO or bile peritonitis. Regardless of the underlying disorder, typical clinical signs are jaundice, acute or chronic vomiting, anorexia, depression, weight loss, and occasionally vague cranial abdominal pain. Because of the protected location of the gallbladder in the abdomen, it is rarely possible to be able to palpate it in a dog with EBDO, unless the gallbladder is greatly enlarged.

### **Diagnosis**

The pattern of clinicopathologic findings typical of biliary tract disorders is that of hyperbilirubinemia, high serum AP and GGT activities, high fasting and postprandial serum bile acid (SBA) concentrations, and less severe changes in serum ALT activity. SBA concentrations increase early in dogs with biliary stasis; in these circumstances the degree of SBA elevation gives no indication of liver function. Generally, more severe cholestatic lesions are associated with more severe clinicopathologic changes. Fractionating the total bilirubin concentration into direct- and indirect-reacting components (i.e., the van den Bergh reaction) does not distinguish intrahepatic from extrahepatic cholestasis or obstructive from nonobstructive cholestasis. Radiographically, there may be evidence of hepatomegaly and a mass effect in the area of the gallbladder on survey abdominal films. Gas shadows associated with the gallbladder and other biliary tract structures could be ascribed to ascending infection with gas-forming organisms. Findings consistent with acute-onchronic pancreatitis as an underlying cause of EBDO are loss of serosal detail in the area of the pancreas as an indication of localized peritonitis, trapped pockets of gas in the duodenum, and duodenal displacement. However, in many cases of chronic pancreatitis imaging findings may be less severe or normal in spite of extensive fibrosis around the bile duct. Choleliths form in dogs in a manner similar to the way they form in cats, usually as a sequela to cholestasis and infection, but they may also be found in asymptomatic dogs. These concretions are radiolucent unless they contain calcium, which occurs about 50% of the time. Inflammatory abdominal effusion is expected in dogs with bile peritonitis but not in those with most causes of EBDO (except for effusions associated with pancreatitis or pancreatic cancer).

The ability to differentiate medical from surgical causes of jaundice has been refined with the development of ultrasonography, although this imaging modality is certainly not foolproof. Dilated and tortuous hepatic bile ducts and CBD, as well as gallbladder distention, are convincing ultrasonographic evidence of EBDO at the CBD or sphincter of Oddi. When dilated biliary structures are seen, it might be difficult to distinguish EBDO that requires surgical intervention from resolving, transient EBDO associated with severe acute-onchronic pancreatitis or from nonobstructive biliary disease (e.g., bacterial cholecystitis/cholangitis) unless a source of obstruction is specifically identified (e.g., pancreatic mass, cholelith in the CBD). Prolonged fasting causes gallbladder enlargement because of delayed evacuation and should not be overinterpreted. In addition, cystic hyperplasia and epithelial polyp formation are common lesions in older dogs, not to be confused with choleliths in the gallbladder. A stellate appearance to the contents of the gallbladder is characteristic of gallbladder mucocele. Monitoring the serum bilirubin concentration to determine when to intervene surgically is not worthwhile because it begins to decline over days to weeks, without relief of obstruction, in both cats and dogs with experimentally induced EBDO. Conversely, in some dogs a significant proportion of bilirubin becomes irreversibly bound to albumin in the circulation ("biliprotein"), resulting in delayed clearance and continued elevation of serum bilirubin concentration for up to 2 weeks after the initial insult has resolved.

### **Treatment and Prognosis**

If the distinction between medical and surgical causes of jaundice is not clear, it is safer to proceed surgically to avoid excessive delays in diagnosis. Surgery is required in dogs with persistent EBDO, bile peritonitis, and gallbladder mucocele. As with any other form of liver disease, it is important to stabilize the patient with fluids and electrolytes and perform a hemostasis profile and platelet count before surgery. Prolonged coagulation times may respond to vitamin K injections (1 mg/kg SQ q24h for 24 to 48 hours before and after surgery), but if not, a plasma transfusion is advisable before surgery to replace clotting factors. If surgery for bile peritonitis is to be delayed, peritoneal drainage should be established to remove noxious, bile-containing abdominal fluid and for lavage. Should a site of obstruction or biliary injury not be identified, at least tissue (i.e., liver, gallbladder mucosa) and bile specimens can be obtained for histopathologic and cytologic evaluation and bacterial culture and sensitivity testing. Any abdominal fluid should be analyzed cytologically and cultured for aerobic and anaerobic bacteria. A liver biopsy specimen should also be obtained in all cases. Typical hepatic histopathologic findings in dogs with early EBDO

are canalicular bile plugs and bile ductular proliferation, with degrees of periportal inflammation and fibrosis in chronic cases. Confounding biliary infection can incite a stronger inflammatory reaction in the periportal region. However, it is impossible to diagnose a primary biliary tract infection from a liver biopsy alone. Aerobic and anaerobic culture and cytological examination of bile are required to diagnosis infectious cholangitis.

Surgical goals are to relieve biliary obstruction or leakage and restore bile flow. Reconstructive procedures to divert bile flow can be performed if the cause of EBDO cannot be corrected. However, because these carry a poor long-term prognosis, less invasive procedures such as stenting are preferred whenever possible (Amsellem et al., 2006).

Antibiotic therapy is started immediately after bile samples are obtained; ampicillin or amoxicillin (22 mg/kg IV, SQ, or PO q8h), first-generation cephalosporins (22 mg/kg IV or PO q8h), or metronidazole (7.5 to 10 mg/kg PO q12h; use lower dose when severe hepatobiliary dysfunction is present) are good empiric choices as single agents initially in animals without a long history of antibiotic administration.

In cases without complete biliary obstruction (e.g., ascending cholangitis) or with transient obstruction (e.g., some cases of acute-on-chronic pancreatitis), medical management alone is indicated. The choleretic ursodiol is indicated as additional treatment in these cases, provided that complete EBDO has been ruled out. The recommended dose is 10 to 15 mg/kg total daily, preferably split into two doses. In addition, all cases (both medical and surgical) should receive antioxidant therapy, preferably with vitamin E (400 IU for a 30-kg dog, scaled appropriately to the size of the dog; tablets usually come as 100 IU, 200 IU, or 400 IU) and S-adenosylmethionine (20 mg/kg PO q24h) because it has been demonstrated that bile reflux in the liver is a potent oxidant toxin. Dogs should be fed a high quality diet which is not protein-restricted: in most cases, a diet designed for critical care feeding is more appropriate than a manufactured liver support diet, because the dog is suffering an inflammatory and/or septic process whereas hepatocyte function is usually good.

The prognosis for dogs with EBDO or bile peritonitis depends on the underlying cause. If the cause can be addressed without surgical reconstruction, the prognosis is fair to good. If extensive biliary reconstruction is needed, the prognosis is guarded.

#### CONGENITAL VASCULAR DISORDERS

Congenital disorders of hepatic vasculature, both intrahepatic and extrahepatic, are more common in dogs than in cats. There are some breed-related tendencies, suggesting a genetic basis to some disorders, but it is also assumed that most of them result from some type of (as yet undefined) insult in utero. It is known that experimental reduction in flow in the umbilical vein in sheep and other species can result in the development of PSSs and asymmetry of hepatic lobular and vascular supplies; this is likely also true in dogs. This would explain why it is relatively common to see dogs with more than one co-existent congenital vascular disorder in the liver (e.g. a congenital PSS combined with intrahepatic portal vein hypoplasia or microvascular dysplasia [MVD]) and would also explain why dogs with congenital PSSs have a higher prevalence of other congenital defects, such as cryptorchidism and cardiac disorders.

For ease of categorization and because they have different clinical presentations, congenital vascular disorders have been divided into disorders associated with low portal pressure and those with high portal pressure. However, it is important to remember than when two or more congenital hepatic defects occur concurrently, the differentiation will be less obvious.

### CONGENITAL VASCULAR DISORDERS ASOCIATED WITH LOW PORTAL PRESSURE: CONGENITAL PORTOSYSTEMIC SHUNT

### **Etiology and Pathogenesis**

Congenital PSSs are the most common congenital portovascular disorder in dogs. The etiology and pathogenesis are very similar to those in cats; the reader is referred to Chapter 37 for more details. Many different types of congenital portovascular anomalies have been reported in dogs; sometimes they co-exist with intrahepatic or extrahepatic portal vein hypoplasia or intrahepatic MVD (discussed in more detail later). However, a distinguishing feature of isolated congenital PSS is that it results in low portal pressure, because some blood is shunted away from the high resistance sinusoidal circulation by the shunting vessel. Dogs with isolated congenital PSS therefore do not present with ascites unless they are severely hypoalbuminemic. This allows differentiation from the congenital vascular disorders associated with increased portal pressure, and therefore acquired PSS, outlined below, in which portal hypertension and associated ascites are common at presentation.

Canine congenital PSS can be extrahepatic or intrahepatic. Extrahepatic PSSs are anomalous vessels connecting the portal vein or one of its contributors (left gastric, splenic, cranial or caudal mesenteric, or gastroduodenal veins) to the caudal vena cava or azygos vein. They are most commonly recognized in small-breed dogs and have a high prevalence in Cairn Terriers, Yorkshire Terriers, West Highland White Terriers, Maltese, Havanese, other terriers, and Miniature Schnauzers (Fig. 38-9). Intrahepatic PSSs may be left-sided, in which case they are thought to represent persistence of the fetal ductus venosus, or they can be right-sided or central, in which case they likely have a different embryological origin. Intrahepatic PSS is more commonly seen in large-breed dogs, but Collies also tend to have extrahepatic PSSs, despite being large dogs. Increased breed prevalence suggests a genetic basis to the disease, but this has only been investigated in Irish Wolfhounds, in which an inherited basis of

**FIG 38-9**Typical small-breed dogs with congenital extrahepatic portosytemic shunts. **A,** An 8-month-old female Border Terrier. **B,** A 9-month-old female Miniature Schnauzer.

patent ductus venosus has been demonstrated, and in Cairn Terriers with extrahepatic PSS, in which an autosomal polygenic inheritance or monogenic with variable expression is suspected (Van Straten et al., 2005). Affected Irish Wolfhounds tend to have smaller litters and can also produce more than one puppy with a PSS in a litter.

One study reported that dogs from breeds that were not usually recognized as having a high risk of PSS were more likely to present with unusual anatomical forms of PSS that were less often amenable to surgical management (Hunt, 2004).

### **Clinical Features**

Clinical signs are very similar to those in cats; neurological, gastrointestinal, and urinary tract signs predominate (see Chapter 37 for more details). About 75% of dogs present before 1 year of age, but some present at an older age, with some as old as 10 years of age before signs are recognized. There is a spectrum of severity of neurological signs ranging from severely affected young puppies that persistently circle, become centrally blind, and can even have seizures or become comatose to very mildly affected individuals. It is likely that this variation reflects differences in shunt fraction and also dietary and other environmental differences among dogs. Polydipsia and polyuria with hyposthenuric urine are relatively common; this is largely due to high cortisol concentration in affected dogs (see Chapter 35) and also increases in antidiuretic hormone and reduced renal medullar concentrating gradient (see Chapter 35). Urate uroliths are also common and can be renal. Anecdotally, urate renal calculi seem to be more common in terriers, and dogs presenting with calculi often do not have prominent neurological signs. On physical examination animals are often (but not always) smaller than their littermates and may have non-localizing

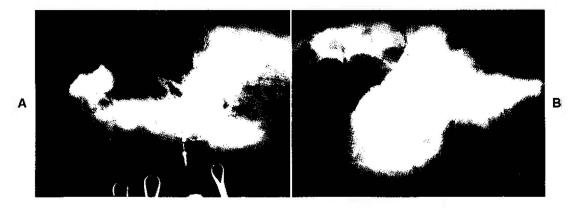

neurological signs and (in some cases) palpable renomegaly. The latter is due to circulatory changes and is not a reflection of renal disease; it is of no clinical significance and regresses after shunt ligation. Other congenital defects may be apparent, particularly cryptorchidism.

#### Diagnosis

Diagnosis of congenital PSS in dogs is the same as in cats (see Chapter 37) and relies on visualizing the shunting vessel ultrasonographically, with portovenography (Fig. 38-10), or grossly at surgery. Scintigraphy can demonstrate shunting but is not helpful to differentiate congenital from acquired PSS, so some other imaging method is necessary for treatment decisions. See Chapter 36 for more information on imaging PSS.

It is important, if possible, to try to estimate how well-developed the remaining hepatic portal vasculature is by repeating the portovenography after ligation and/or by evaluating the histological findings on liver biopsies taken at the time of ligation. This is a work in progress, but there is a strong suspicion that the prognosis postligation may depend on the potential for the intrahepatic vasculature to open up after surgery and that dogs that do poorly postoperatively may have concurrent portal vein hypoplasia and/or MVD (discussed in more detail later).

Nonspecific clinicopathologic findings in more than 50% of affected dogs, regardless of the type of vascular anomaly, are microcytosis, hypoalbuminemia, mild increases in serum AP and ALT activities, hypocholesterolemia, and low BUN concentration. Fasting bile acid concentrations may be normal or high, but postprandial bile acid concentrations are high in all cases. However, this does not distinguish congenital PSS from acquired PPS or early cholestasis, which also causes increases in bile acid concentrations. Postpran-

**A,** Portovenogram in a 1-year-old Golden Retriever with an intrahepatic portosystemic shunt. This was a central divisional shunt and had a venous sinus-like structure, as demonstrated well in this radiograph. **B,** Normal portovenogram in a dog for comparison. (Courtesy the Diagnostic Imaging Department, the Queen's Veterinary School Hospital, University of Cambridge.)

dial ammonia concentration can also be measured and will be high, whereas fasting ammonia concentration may be high or normal (see Box 36-1 for details of how to perform an ammonia challenge test). Ammonia tolerance or challenge tests are potentially dangerous because they can precipitate an encephalopathic crisis. Other tests have been evaluated for their sensitivity and specificity in the diagnosis of PSS. Protein C, a liver-derived anticoagulant factor, is also decreased in dogs with PSS and increases after ligation; this can help differentiate PSS from MVD.

Puppies of high-risk breeds could be screened for congenital PSS by measuring bile acid or ammonia concentrations before they are placed into homes, but there are potential false positives with both of these tests and no puppy should be euthanized or labeled as having a definite congenital PSS on the basis of high bile acid and/or ammonia concentrations without further evidence. Normal Irish Wolfhounds can have a transiently high blood ammonia concentration between the ages of 6 to 8 weeks; this normalizes at 3 to 4 months of age. Zandlivet et al. (2007) have demonstrated that this is due to a clinically insignificant urea cycle defect. Postprandial bile acid concentrations can be falsely elevated in Maltese puppies without PSS for unknown reasons, again confusing any efforts at screening tests in this breed (Tisdall et al., 1995).

On diagnostic imaging the liver is frequently (but not always) small. Ultrasonography now has a high sensitivity and specificity for the diagnosis of both intrahepatic and extrahepatic PSS; furthermore, their anatomy can usually also be described ultrasonographically.

### **Treatment and Prognosis**

Surgical occlusion of the anomalous vessel to restore normal portal circulation has long been recommended as the treatment of choice. In many cases this will restore normal or near normal liver function. However, owners need to be aware of the small but definite risk of postoperative mortality as a result of portal hypertension and/or refractory seizures and of the potential that the PSS may be only partially and not totally ligated. In fact, it is more common to be able to partially ligate the PSS at the first surgery because the portal vasculature cannot initially accommodate all the shunting blood. In some cases it is possible to repeat the surgery at a later date to ligate the PSS further, but this is often not necessary to control clinical signs. A few dogs with partially ligated shunts develop portal hypertension and multiple acquired PSS with a recurrence of their clinical signs. There are several different surgical procedures described for ligation of PSS, but they are outside the scope of this book. In addition to surgical ligation, PSS may be attenuated with ameroid constrictors (Fig. 38-11) or embolized with coils. Laparoscopic ligation of PSS has been reported in two dogs (Miller et al., 2006). Ligation of a PSS requires an experienced surgeon.

Medical management is required to stabilize the patient before surgery and also for about 8 weeks after surgery while the hepatic vasculature and mass recover. This involves careful dietary management combined, in many cases, with antibiotics and soluble dietary fiber. The details are outlined in Chapter 39. In some cases medical management may continue successfully over the course of the patient's life as an alternative to surgery (Watson et al., 1998). Usually, this is because the client cannot afford referral or is unhappy about the risks associated with surgery or because the patient has multiple or intrahepatic shunts. Mildly affected and older animals are good candidates for medical management; generally, these are the individuals with smaller shunting fractions. Dogs (particularly terriers) that present at an older age with urate stones but no neurological signs, are also good candidates for medical management alone. In addition, dogs with concurrent portal vein hypoplasia and/or MVD tend to have a higher surgical risk and are best managed medically.

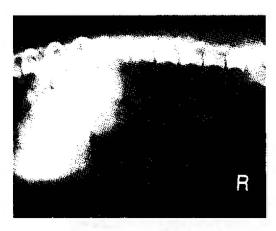

FIG 38-11

Lateral abdominal radiograph of a 3-year-old Miniature Schnauzer that had an extrahepatic portosystemic shunt ligated with an ameroid constrictor 2 years previously. Note the ameroid is visible as a radiodense ring in the craniodorsal abdomen. (Courtesy the Diagnostic Imaging Department, the Queen's Veterinary School Hospital, University of Cambridge.)

Medical management does not reverse the underlying disorder but can result in good long-term results. Once the dog has reached adulthood, there is no evidence that the liver progressively atrophies throughout life. Ultimately, more studies are needed to identify the factors that are most important in determining prognosis after medical and/or surgical management and to help identify preoperatively the small number of animals that will have a poor outcome after surgery.

# CONGENITAL VASCULAR DISORDERS ASSOCIATED WITH HIGH PORTAL PRESSURE

There are a number of less common congenital vascular disorders of the liver in dogs that present with normal or high portal pressure, rather than the low portal pressure seen in association with congenital PSS. Because of the portal hypertension, the affected dog may present with the constellation of typical clinical signs (see Chapter 39), including ascites, and the potential for GI ulceration in addition to multiple acquired PSS and HE. With the exception of arteriovenous fistulae, none of these conditions can be treated surgically; however, some of them have a good long-term prognosis with medical management.

### Primary Hypoplasia of The Portal Vein/ Microvascular Dysplasia/Noncirrhotic Portal Hypertension

### **Etiology and Pathogenesis**

There are several reports of vascular disorders in young dogs associated with portal hypertension, usually ascites, and characteristic histopathological changes in the liver of a reduction in smaller portal vein branches, increased numbers of arterioles, and a variable amount of mild fibrosis. There are some reports of overt hypoplasia of the extrahepatic portal vein, but most reports of noncirrhotic portal hypertension and MVD appear to describe portal vein hypoplasia confined to the intrahepatic vasculature. These diseases may all be different abnormalities or they may represent different spectra of the same abnormalities, but their clinical presentation, treatment, and prognosis are similar. A lack of intrahepatic or extrahepatic portal vein branches results in portal hypertension, with the same potential consequences as those of chronic hepatitis (see preceding section), including ascites, gut wall edema, and often GI ulceration and acquired PSS. Dogs with MVD often do not present with notable portal hypertension, but it is grouped with these diseases by the WSAVA liver standardization group (Cullen et al., 2006). Dogs reported with MVD typically have shunting at the level of the hepatic lobule but do not have clinical signs of overt portal hypertension.

Any breed can be affected, but MVD particularly affects small-breed dogs, with Yorkshire Terriers and Cairn Terriers showing a particularly high incidence.

### **Clinical Signs**

Dogs with all these conditions typically present at a young age with a combination of signs of portal hypertension and PSS, the severity of which depends on that of their lesions. Because of the acquired PSS seen in these patients, some of the clinical signs and clinicopathologic findings overlap with those of congenital PSS, particularly because all these disorders typically present in young dogs. Therefore presence of other signs of portal hypertension (e.g., ascites) is an important clinical clue that one of these disorders with acquired PSS may be present, rather than a congenital PSS.

Dogs with portal vein hypoplasia or idiopathic noncirrhotic portal hypertension typically present between 1 and 4 years of age and are often purebreds of either gender; large breeds predominate. Early reports of "congenital" or juvenile hepatic fibrosis in German Shepherd Dogs may also have represented a form of noncirrhotic portal hypertension. Presenting signs are typically those of portal hypertension, with abdominal distention associated with effusion; GI signs; polydipsia; weight loss; and, less consistently, signs of HE. Dogs are often surprisingly alert (Fig. 38-12).

Dogs with MVD present with similar clinicopathological findings but usually without overt evidence of portal hypertension or ascites. MVD tends to affect terriers and thus overlaps with breeds at high risk for congenital PSS. In addition, some dogs may have both congenital PSS and MVD or portal vein hypoplasia, further confusing the diagnosis. Cairn Terriers and Yorkshire Terriers in particular have been reported with MVD. In one breed (the Cairn Terrier), the site of anatomic abnormality has been identified as the terminal portal veins. In this breed it is believed to be an autosomal, inherited trait, but the specific mode of inheritance has not been established. Typical signs include vomiting, diarrhea, and signs of HE, although the clinical signs, particularly the HE, are notably milder in dogs with MVD than

#### FIG 38-12

A female German Shepherd Dog with noncirrhotic portal hypertension. **A,** At 14 months of age, with ascites and in poor body condition but remarkably alert **B,** 5 years later on medical management only—very stable and in good body condition with no detectable ascites. The dog lived for 8 years with a good quality of life before developing a gastroduodenal ulcer (see Chapter 39). **C,** Drugs that the dog received long term, in addition to dietary management. (B and C reproduced by permission from *UK Vet*, 9(7):41, 2004.)

in those with congenital PSS unless both disorders occur concurrently. Dogs with only MVD are somewhat older, and many have mild to no signs of illness. In the case of young purebred dogs that have been screened for congenital PSS before sale or that are ill for nonhepatic reasons, high SBA concentration may be the only finding.

#### **Diagnosis**

Diagnosis of MVD/intrahepatic portal vein hypoplasia and noncirrhotic portal hypertension relies ultimately on liver biopsy findings of intrahepatic portal vein hypoplasia in the absence of a grossly demonstrable shunting vessel. The liver biopsy findings alone can be indistinguishable from the changes that occur secondary to congenital PSS, and therefore the clinical findings of concurrent portal hypertension and ruling out a shunting vessel are important parts of the final diagnosis. Clinicopathologic findings are very similar to those in dogs with congenital PSS and include microcytosis, evidence of hepatic dysfunction (e.g., hypoalbuminemia), and low urine specific gravity. Microhepatia and hypoechogenic abdominal fluid are the notable abdominal ultrasonographic findings in dogs with noncir-

rhotic portal hypertension; it may be possible to visualize multiple acquired PSSs ultrasonographically. Dogs with MVD alone tend not to have ascites and have less marked increases in SBA concentrations than dogs with true congenital PSS.

The most important aspects of identifying a dog with MVD/portal vein hypoplasia/noncirrhotic portal hypertension are ruling out a surgically correctable PSS, identifying portal hypertension (which requires treatment, see Chapter 39), and obtaining a liver biopsy for confirmation or exclusion of other hepatopathies. Portal vein hypoplasia and noncirrhotic portal hypertension are very similarly clinically, on clinical pathology, and on diagnostic imaging to end-stage chronic hepatitis with cirrhosis, and the only way to differentiate the two is on liver histology. In general, portal vein hypoplasia/noncirrhotic portal hypertension carries a much better long-term prognosis than cirrhosis, so the differentiation is important prognostically.

#### **Treatment and Prognosis**

The prognosis for all these conditions appears to be relatively good, provided the clinical signs can be controlled. They are

nonprogressive, and there is no surgical treatment for any of them; symptomatic therapy of HE, ascites, and GI ulceration (if present) is usually successful (see Chapter 39). It should be noted that glucocorticoid therapy is absolutely contraindicated in these dogs and is likely to worsen the outcome because of the associated portal hypertension and high risk of GI ulceration. This underlines the importance of liver biopsy in these dogs, allowing differentiation from chronic hepatitis.

One study of dogs with noncirrhotic portal hypertension concluded that affected dogs might live as long as 9 years after diagnosis with appropriate symptomatic therapy. A few dogs were euthanized because of problems related to persistent portal hypertension (e.g., duodenal ulceration). Dogs with MVD tend to have milder clinical signs than dogs with congenital PSS and can be managed medically with success over the long term. Affected dogs seem to live comfortably in good to excellent condition for at least 5 years (Christiansen et al., 2000).

### Arterioportal Fistula

Intrahepatic arterioportal fistula, causing marked volume overload of the portal circulation resulting in portal hypertension, acquired PSSs, and ascites, is seen occasionally. Abdominal ultrasonography with Doppler can frequently detect the tortuous tubular structures representing the connection between an artery and overperfused portal vein or veins; sometimes the turbulent blood flow through the fistula can be auscultated through the body wall. If only one lobe of the liver is affected, the lobe containing the arterioportal fistula can be removed surgically; assuming that there is adequate intrahepatic portal vasculature, acquired PSSs regress once portal overcirculation subsides. More often, multiple liver lobes are involved, making surgical treatment impossible.

### **FOCAL HEPATIC LESIONS**

### **ABSCESSES**

### Etiology

Hepatic abscesses are usually the result of septic embolization from an intraabdominal bacterial infection. In puppies they are a frequently a consequence of omphalophlebitis, whereas in adult dogs they arise most often subsequent to inflammatory conditions of the pancreas or hepatobiliary system. Adult dogs with certain endocrine diseases, such as diabetes mellitus or hyperadrenocorticism, are also at risk. Occasionally, infection arising from a location other than the abdominal cavity, such as the endocardium, lung, or blood, may disseminate to the liver, causing abscessation.

In a review (Farrar et al., 1996) of 14 dogs with hepatic abscesses, aerobic bacteria were isolated in 9 of 10 cases in which material from the hepatic lesions was submitted for culture. Although the most common isolates were gramnegative organisms, *Staphylococcus* spp. were identified in

two dogs. *Clostridium* sp. was the only isolate cultured anaerobically from abscess fluid in 4 of 7 dogs.

#### **Clinical Features**

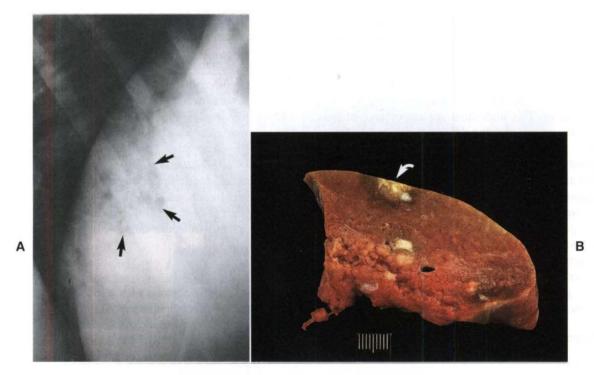

The typical signalment and physical examination findings in dogs with hepatic abscesses depend on the underlying cause. Dogs over 8 years old are most often affected because the predisposing causes of liver abscesses are seen more commonly in older dogs. Regardless of the initiating event, anorexia, lethargy, and vomiting are consistent presenting complaints. Expected physical examination findings include fever, dehydration, and abdominal pain. Hepatomegaly may be detected in dogs with diabetes mellitus or hyperadreno-corticism and in some dogs with primary hepatobiliary disease.

### Diagnosis

Neutrophilic leukocytosis with a left shift, with or without toxic changes, and high serum ALP and ALT activities are dependable but nonspecific clinicopathologic abnormalities. Survey abdominal radiographs may reveal evidence of irregular hepatomegaly, a mass, or gas opacities within the area of the hepatic parenchyma (Fig. 38-13), but ultrasonography is the imaging modality of choice. One or more hypoechoic or anechoic hepatic masses and perhaps a hyperechoic rim surrounding the mass or masses are characteristic findings. If there are multiple masses that would preclude surgical removal or if the owner declines surgery, FNA cytologic analysis of the contents of a representative lesion will distinguish an abscess from nodular hyperplasia, neoplasm (e.g., hemangiosarcoma), or granuloma. Ideally, material should be obtained for cytologic analysis and aerobic and anaerobic bacterial culture from a representative lesion deep in the liver parenchyma to prevent abscess rupture and abdominal contamination. Abscess material should also be obtained by this approach during surgery so that antibiotic treatment can be initiated postoperatively. Ultrasound-guided drainage of the abscess can also be used as treatment in combination with appropriate antibiotics (discussed in more detail later). Results of the preliminary clinicopathologic and radiographic evaluation should be scrutinized for evidence of previously mentioned associated or predisposing illnesses.

### **Treatment and Prognosis**

Treatment for liver abscesses consists of surgical removal of infected tissue, administration of appropriate antibiotics, supportive care, and resolution of underlying predisposing conditions. Infected liver tissue should be removed, if possible, and submitted for histopathologic examination and bacterial culture if this was not done preoperatively. Fluid, electrolyte, and acid-base abnormalities are addressed. Administration of a combination of antibiotics with a gramnegative and anaerobic spectrum is initiated until culture and sensitivity test results are available. Because staphylococci and clostridia are the most common isolates, amoxicillin (10 to 20 mg/kg IV q8h) or enrofloxacin (2.5 mg/kg IV or PO q12h) combined with metronidazole (10 mg/kg PO

**FIG 38-13 A,** Lateral abdominal radiograph of a 1-year-old female Great Dane with a liver abscess (arrows) caused by Clostridium spp.; the cause was undetermined. **B,** Gross appearance of the resected liver lobe containing an abscess (arrow).

q8-12h or 7.5 mg/kg PO q8-12h for dogs with hepatic dysfunction) or clindamycin (10 mg/kg IV or PO q12h) is a good empiric choice. Surgery is not indicated in animals with multiple abscesses; ultrasound-guided centesis and abscess evacuation may be a reasonable adjunct to treatment. Antibiotic treatment is continued on a long-term basis, usually for 6 to 8 weeks or until clinicopathologic and ultrasonographic indicators of abscessation are resolved. From the limited information available about this rare condition, it seems that with aggressive medical and surgical management the prognosis for dogs with liver abscesses may not be as poor as once thought.

#### **NODULAR HYPERPLASIA**

Hepatic nodular hyperplasia is a benign condition of older dogs that does not cause clinical illness; clinicians should be aware of it, however, because hyperplastic nodules may be misinterpreted as a more serious condition, such as primary or metastatic malignancy or regenerative nodules associated with cirrhosis. The prevalence increases with age, and as many as 70% to 100% of dogs older than 14 years of age have some microscopic or macroscopic hyperplasia. Affected dogs have high serum ALP activity (usually 2.5-fold elevation but may be as high as fourteenfold), which prompts investigation for hyperadrenocorticism. There is no evidence of hepatic dysfunction on serum biochemical analysis. Many dogs have multiple macroscopic nodules found ultrasonographically or at surgery, ranging in size from 2 to 5 cm in diameter; some dogs have a single nodule. Micronodular

change occurs much less frequently and would be identified in liver biopsy specimens. The lesion consists of increased numbers of normal to vacuolated hepatocytes with more mitotic figures and fewer binucleate cells than expected in normal liver; components of normal lobular architecture (e.g., portal tracts, central vein) remain. Adjacent parenchyma is compressed by growth of the nodules; fibrosis, necrosis, inflammation, and bile ductule hyperplasia are absent. Because the prognosis for each of these nodular conditions is different and the margin of the lesion with adjacent hepatic tissue is important to establish a diagnosis, a wedge biopsy is recommended. Needle specimens are likely to be too small to confidently differentiate nodular hyperplasia from primary hepatocellular carcinoma or adenoma. The cause of this lesion is unknown; on the basis of experimental development of nodular hyperplasia in rodent species, some have speculated a dietary role (low protein).

#### **NEOPLASIA**

### Etiology

Primary hepatic neoplasms are rare in dogs, accounting for fewer than 1.5% of all canine tumors. Unlike in cats, malignant tumors are more common than benign tumors, and metastatic tumors are 2.5 times more common than primary tumors in dogs. Metastases particularly arise from primary neoplasms in the spleen, pancreas, and GI tract (Fig. 38-14); the liver can also be involved in systemic malignancies such as lymphoma, malignant histiocytosis, and mastocytosis.

Although certain chemicals can induce hepatic neoplasms experimentally and infectious hepatitis is also a predisposing cause in other species, the cause of naturally occurring canine hepatic neoplasms is unknown. The types of primary hepatic tumors seen in dogs and their relative importance and metastatic potential are outlined in Table 38-3.

### **Clinical Features**

Clinical signs and physical examination findings in dogs with primary or secondary liver tumors are nonspecific, except for diffuse or nodular hepatomegaly. Even this can be confused with other conditions, such as macronodular cirrhosis or benign nodular hyperplasia, which are also common in older dogs. Therefore no dog should be euthanized on the basis of a presumptive diagnosis of a liver mass on clinical

FIG 38-14
Gross appearance of liver post-mortem from a 2-year-old male Husky with a metastic carcinoma.

examination or diagnostic imaging without supportive histology. The left liver lobes are often affected by hepatocellular carcinoma which can occur in three different patterns: massive (single, large nodule; most common), nodular (multiple smaller nodules), and diffuse (indistinct nodules throughout). The behavior of each type of tumor tends also to be different, as outlined in Table 38-3.

Clinicopathologic abnormalities are likewise not specific for neoplasia and blood tests may be normal, even in dogs with extensive involvement. Dogs with lymphoma infiltrating the liver usually have marked increases in ALT and ALP activities but are rarely jaundiced; moreover, they may have normal liver echotexture. Hypoglycemia has been described in association with hepatocellular carcinoma in dogs and can be due to paraneoplastic production of insulin-like growth factor. Massive forms of hepatocellular carcinoma have a low metastatic rate. Metastases from other diffuse and nodular forms of hepatocellular carcinoma or biliary carcinoma usually occur early; the most common sites are regional lymph nodes, lung, and peritoneal surfaces. Hepatocellular adenoma (hepatoma) is a benign tumor that most often occurs as a single mass that is typically smaller than the massive form of hepatocellular carcinoma but can be multifocal. Histologic features of hepatocellular adenoma are very similar to those of nodular hyperplasia (or indeed normal liver) except for the presence of a fine rim of reticulin surrounding the adenoma and lack of apparent normal architecture (i.e., few portal tracts, no central veins).

### Treatment and Prognosis

When a single large hepatic mass is identified, it can be very difficult to distinguish well-differentiated hepatocellular carcinoma from nodular hyperplasia and hepatocellular

**TABLE 38-3** 

### Primary Liver Tumors in Dogs

Note that malignant tumors are more common than benign tumors and that metastases to the liver are more common than primary liver tumors in dogs.

### TYPE OF TUMOR

Hepatocellular tumors: Hepatocellular carcinoma (HCC) Hepatocellular adenoma/hepatoma (Hepatoblastoma—very rare)

Biliary tract tumors:

Biliary carcinoma (including cystadenocarcinoma) Biliary adenoma Gallbladder tumors

Neuroendocrine tumors:

Hepatic carcinoid

Primary hepatic sarcomas:

Hemangiosarcoma, leiomyosarcoma, and others

### COMMENTS

HCC most common primary liver tumor in dogs (50%). Most are massive; some are nodular or diffuse. Miniature Schnauzers and male dogs may be at increased risk. MR 0% to 37% for massive and 93% to 100% for nodular and diffuse forms.

Adenoma uncommon and usually incidental.

Bile duct carcinomas second most common primary tumor in dogs (22% to 41% of malignant canine liver tumors). Labrador Retrievers and females may be at increased risk. Usually aggressive. MR up to 88%. Adenomas uncommon and gallbladder tumors very rare. Very rare, but always diffuse or nodular, and very aggressive.

Uncommon. Most locally aggressive, diffuse or nodular and high MR.

adenoma. Surgical resection is the treatment of choice for primary hepatic neoplasms and for massive hepatocellular carcinoma. In the latter, it usually carries a good prognosis because they have a lower metastatic rate than the more diffuse and nodular forms of the tumor and local recurrence rate after liver lobectomy is reportedly less than 13%. Longterm (2- to 3-year) survival rates after surgical resection are common in dogs with massive hepatocellular carcinoma Surgical excision is therefore the treatment of choice for single tumors involving one liver lobe because this allows both diagnosis and, in many cases, cure. The prognosis for diffuse and nodular hepatocellular carcinoma and other forms of primary malignant liver tumors is poor because there is no effective therapy. Radiation therapy is not effective because the liver cannot tolerate cumulative doses of radiation. Hepatic tumors also respond poorly to chemotherapy, likely partly because of development of rapid drug resistance by neoplastic hepatocytes. The response of secondary (metastatic) liver tumors depends on the type and location of the primary; responses in dogs with lymphoma are very good to excellent, and in dogs with hemangisoarcoma they are good. Metastatic carcinomas or carcinoids of the liver rarely respond to chemotherapy.

### HEPATOCUTANEOUS SYNDROME/ SUPERFICIAL NECROLYTIC DERMATITIS

### **Etiology and Pathogenesis**

Hepatocutaneous syndrome (also known as superficial necrolytic dermatitis, metabolic epidermal necrosis, and necrolytic migratory erythema) is a skin condition reported in association with certain liver diseases that usually carries a poor prognosis. The pathophysiology and underlying causes in dogs remain unclear, and it is likely multifactorial. It occurs in association with certain classical findings on hepatic ultrasonography and histopathology, and often no underlying cause is found. However, because it is likely that many cases represent a hepatic reaction to an underlying endocrine tumor or disorder, superficial necrolytic dermatitis represents an intermediate disorder between primary liver disease and secondary hepatopathies.

The underlying pathogenesis in the skin appears to be due to abnormally low circulating amino acid concentrations and thus malnutrition of the skin, particularly in areas of poor blood supply, such as the extremities. Zinc deficiency may also be involved because the histological appearance of the skin is very similar to that in dogs with zinc-responsive dermatosis; fatty acid deficiencies have also been implicated. In humans the disorder is usually associated with a glucagon-secreting tumor of the pancreas. However, glucagonomas are rarely reported in affected dogs, and circulating glucagon concentrations are usually normal (although they may be occasionally high). Plasma amino acid concentrations have been reported to be very low in all affected dogs in which they have been measured, both in dogs with pan-

creatic tumors and dogs without. It has been proposed that canine superficial necrolytic dermatitis represents a metabolic hepatopathy with increased hepatic catabolism of amino acids that decreases their peripheral availability.

Recently, 11 dogs with superficial necrolytic dermatitis secondary to chronic phenobarbital administration for epilepsy were reported (March et al., 2004). The median age of the affected dogs was 10 years, and the median duration of phenobarbital therapy was 6 years. No other underlying cause could be found. Plasma amino acid concentrations were markedly decreased in the only dog in which they were measured.

Whatever the underlying pathogenesis, dogs with superficial necrolytic dermatitis are at high risk of becoming diabetic, which is reported in 25% to 40% of cases. This is easy to explain if blood glucagon concentrations are high, because glucagon is a diabetogenic hormone, but is difficult to explain on the basis of simple amino acid alterations.

### **Clinical Findings**

Idiopathic superficial necrolytic dermatitis is reported most often in older dogs of small breeds; in one study 75% of the affected dogs were male (Outerbridge et al., 2002). Most dogs present because of their skin disease rather than their primary liver disease. Typically, there is erythema; crusting; and hyperkeratosis affecting the footpads, the nose, and periorbital, perianal, and genital areas and also often pressure points on the limbs. The paw lesions can be extremely painful because of associated fissures and may result in lameness and secondary infection. Signs of liver disease may also be present (although usually not), and diabetes mellitus often develops later in the disease process, especially if the animal is given diabetogenic drugs such as glucocorticoids in an attempt to control the skin disease.

### **Diagnosis**

Definitive diagnosis is based on skin biopsy findings that are very characteristic and unique: The only syndrome with a similar appearance on skin histopathology is zinc-responsive dermatosis. There is a marked parakeratotic hyperkeratosis with intercellular and intracellular edema and hyperplastic basal cells, producing a characteristic "red, white, and blue" appearance on hematoxylin and eosin staining.

The associated hepatic findings are more nonspecific, except for the ultrasonographic findings. There are usually increases in liver enzyme activities, and there may be hypoalbuminemia in some cases. In dogs that are diabetic there is hyperglycemia and glycosuria. The classical ultrasonographic appearance is a "Swiss-cheese" liver consisting of multiple hypoechoic regions with hyperechoic borders (Fig. 38-15). Hepatic histology in all cases is remarkably similar, showing what has been described as a distinctive form of macronodular cirrhosis. The liver is divided into regenerative hyperplastic nodules with fibrous septa and bordered by characteristic ballooned, vacuolated hepatocytes but with minimal or no inflammation or necrosis.

### FIG 38-15

Note the typical hypoechoic "holes" in the liver parenchyma on the left. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge.)

### **Treatment and Prognosis**

The prognosis is very poor unless the underlying cause can be identified and treated; most dogs live for less than 6 months. There have been reports of resolution of disease if a pancreatic tumor is identified and removed. Dogs with phenobarbital-associated hepatocutaneous syndrome may improve when the drug is withdrawn, although this has not yet been demonstrated. An alternative nonhepatotoxic therapy for their epilepsy will need to be instituted; potassium bromide might be an alternative choice, but it takes weeks to reach steady-state. Gabapentin might also be used, although this is only effective in some dogs. For additional information, please see Chapter 67.

When an underlying cause cannot be identified and treated, therapy is symptomatic and supportive. The most important aspect is amino acid/protein supplementation; in a few cases this may lead to long-term survival. There are single case reports of humans with resolution of the disease after amino acid infusions and/or regular dietary supplementation of egg protein; feeding egg yolks has also been reported as resulting in a clinical improvement in some dogs. It is unclear whether eggs are beneficial simply because they are a high-quality amino acid supplement or whether there are other beneficial micronutrients in the eggs. Dogs with hepatocutaneous syndrome should not be fed proprietary diets for liver disease because these are protein restricted. Other support included antibiotics for secondary skin infections (such as cefalexin 20 mg/kg q12h) and antioxidants (see the section on the treatment of chronic hepatitis). In addition, zinc and fatty acid supplementation may be helpful in some cases. Glucocorticoids should be avoided because they will precipitate diabetes mellitus. We have treated two dogs with hepatocutaneous syndrome that survived for several years on a high-quality digestible diet (marketed for GI disease) supplemented with extra egg and vitamin E and S-adenosylmethionine supplementation with antibiotics; however, one dog did become diabetic a month after diagnosis.

### **SECONDARY HEPATOPATHIES**

Secondary (reactive and vacuolar) hepatopathies are very common in dogs. In fact, in pathology studies it is clear that they are more common than primary hepatic disease. Many of these hepatopathies result in elevations in liver enzymes, but the liver changes are usually not clinically significant and usually do not result in compromised liver function. However, they are often confused with primary liver disease, and it is important to rule out secondary hepatopathies as much as possible in the workup of dogs with elevated liver enzymes to allow identification and treatment of the underlying primary disease (e.g., endocrine disease or inflammatory disease elsewhere in the splanchic bed). It is also important to be aware that raised liver enzymes in an old dog have many other causes apart from primary liver disease and to resist the tendency to immediately put such dogs on a protein-restricted diet and other medication for liver disease before working up the case properly. Many dogs with secondary hepatopathies will not have hepatic histopathology performed because the primary cause will be identified with other tests. However, it is convenient from a classification point of view to split secondary hepatopathies into three groups on the basis of their appearance histopathologically: secondary hepatopathies associated with hepatocyte swelling and/or vacuolation, hepatic congestion/edema, and reactive hepatitis.

### **HEPATOCYTE VACUOLATION**

Secondary hepatopathies associated with hepatocyte vacuolation are divided into steroid-induced hepatopathy and hepatocellular steatosis (lipidosis/fatty change). Steroid-induced hepatopathy is characterized by hepatocellular glycogen accumulation, which is distinctive from steatosis, in which fat (rather than glycogen) accumulates in hepatocytes. The difference can be demonstrated with special stains (Periodic acid Schiff for glycogen and Oil red O or Sudan black for fat), but there are some differences also on routine hematoxylin and eosin staining that help with differentiation: Glycogen vacuoles tend not to displace the nucleus from the center of the cell and often contain strands of eosinophilic material, whereas classic steatosis is associated with clear, empty vacuoles (because the fat is lost in processing) and the nucleus is often displaced to the edge of the cell (Fig. 38-16).

Both types of vacuolar hepatopathy are reversible when the underlying cause is taken away. The most common causes are endocrine diseases (see Table 38-1). Steroid-induced hepatopathy is seen in hyperadrenocorticism and dogs being given exogenous corticosteroids. It has also been associated with other hormone therapies and administration of some other drugs, such as D-penicillamine. There have been

FIG 38-16

Gross (A) and histological (B) appearance of the liver postmortem in a middle-aged Miniature Poodle with poorly controlled diabetes mellitus. Note the pale, yellowish appearance of the liver associated with generalized hepatic steatosis. Histologically, the hepatocytes are markedly swollen with fat that displaces the nuclei to the edge of the cells. Portal triad in the center (Hematoxylin and eosin x 200). (Courtesy Pathology Department, Department of Veterinary Medicine, University of Cambridge.)

reports of idiopathic vacuolar hepatopathy in Scottish terriers causing marked elevations in ALP, but the underlying cause is unknown. The vacuolation seen as part of the hepatocutaneous syndrome looks very similar to glycogen vacuolation. Steatosis is classically associated with diabetes mellitus in dogs, in which it starts centrilobularly and then spreads. It has also been reported in juvenile hypoglycemia of small-breed dogs. However, although hepatic steatosis can sometimes appear very marked in dogs, it does not appear to become a clinically significant disease in its own right, unlike in cats, in which primary or secondary hepatic lipidosis are important clinical syndromes (Chapter 37).

#### **HEPATIC CONGESTION/EDEMA**

Hepatic congestion is a common finding with right-sided congestive heart failure and other causes of posthepatic venous congestion, such as heartworm disease. This results again in elevation in liver enzymes. It is usually reversible, but in a few very chronic cases of congestion associated with heart disease, it can result in fibrosis and permanent compromise ("hepatic cirrhosis").

### **NONSPECIFIC REACTIVE HEPATITIS**

Nonspecific reactive hepatitis is a nonspecific hepatic response to a number of extrahepatic processes, particularly inflammatory processes in the splanchic bed such as pancreatitis and inflammatory bowel disease. There is a mild inflammatory infiltrate in the sinusoids and portal areas and/or parenchyma but no associated hepatocyte necrosis or fibrosis and therefore no evidence of primary (significant) hepatitis. This could be viewed as the hepatic equivalent of a "reactive lymph node" and should stimulate a search for an underlying cause.

#### **Diagnosis**

The diagnosis of all types of secondary hepatopathy relies on diagnosing the underlying cause. The clinical signs will be those of the primary cause and not related to the liver. However, sometimes there will be an overlap in clinical signs—notably with hyperadrenocorticism or diabetes mellitus in which the polydipsia, poluria, and abdominal enlargement together with raised liver enzymes might increase the suspicion of primary liver disease. Recognizing that there is a secondary hepatopathy involves initial pattern recognition of the enzyme elevation and clinical signs (e.g., in a dog with polydipsia/polyuria, a pot-belly, and dermatological signs, a pattern of a very marked elevation in ALP and less marked elevation in ALT should raise the suspicion of hyperadrenocorticism). This is followed by appropriate diagnostic tests for the underlying condition. Liver biopsies are usually not indicated or taken. However, there will inevitably be cases with mild or nonclassical changes of the primary condition in which liver biopsies will be taken on suspicion of primary hepatopathy. Finding nonspecific secondary changes in the liver should then stimulate a repeat search for an underlying cause.

### CHAPTER OUTLINE

GENERAL CONSIDERATIONS HEPATIC ENCEPHALOPATHY

Chronic Hepatic Encephalopathy Acute Hepatic Encephalopathy PORTAL HYPERTENSION

Splanchnic Congestion and Gastrointestinal Ulceration

Ascites

COAGULOPATHY

PROTEIN-CALORIE MALNUTRITION

### **GENERAL CONSIDERATIONS**

The following problems are common in dogs with hepatic failure and are usually related to sudden or chronic progressive loss of functional hepatocyte mass, intrahepatic portal hypertension resulting from primary hepatobiliary disease, acquired portosystemic shunts (PSSs), or a combination of these factors. The clinical syndrome of portal hypertension with abdominal effusion, acquired PSSs, and high risk of gastrointestinal (GI) ulceration is observed frequently in dogs with chronic liver disease but rarely in cats, whereas coagulopathies are common in cats because of the additional effects of concurrent biliary tract, pancreatic, and small intestinal disease. Hepatic encephalopathy (HE) resulting from congenital PSS is relatively common in both species. Protein-calorie malnutrition is common in both species, particularly in association with chronic disease. Effective management of these problems is vital to achieve a reasonable quality of life for the patient and to enable hepatic recovery while specific therapy is taking effect or when the underlying cause cannot be eradicated.

### HEPATIC ENCEPHALOPATHY

### CHRONIC HEPATIC ENCEPHALOPATHY

#### **Treatment**

The goal of treatment in cats and dogs with HE is to restore normal neurologic function by decreasing formation of gutderived and peripherally derived encephalotoxins, eliminating precipitating factors, and correcting acid-base and electrolyte abnormalities. A variety of encephalotoxins are implicated in causing HE (see Chapter 35), but the most important from the point of view of treatment is ammonia. It was once believed that the most important source of ammonia was undigested protein in the gut, but emphasis has now shifted to interorgan metabolism of ammonia in patients with HE, whereas dietary protein itself is a less important source (Wright et al., 2007; see Chapter 35). Inflammatory mediators are also thought to be important precipitators of HE in their own right. It is known that clinically relevant episodes of HE in dogs and cats with congenital or acquired PSS are often precipitated not just by feeding but also by stress and infections, emphasizing the role of hypermetabolism, inflammation, and breakdown of body protein in the development of HE. In fact, particularly in dogs with acquired PSS and protein-calorie malnutrition, HE is often triggered by negative nitrogen balance and breaking down muscle mass (Fig. 39-1), and in these circumstances starvation and protein restriction will worsen the HE.

A combination of careful dietary manipulation, locally acting agents that discourage formation of readily absorbable ammonia and hasten evacuation of the intestinal tract, antibiotics to suppress bacterial populations that generate ammonia and other gut-derived encephalotoxins, and treatment of any precipitating cause is the standard approach for long-term management of chronic HE (Box 39-1). Dietary management and treatment of the underlying cause are the most important approaches, but advice has changed over the last few years with respect to protein restriction, and it is now clear that dogs and cats with congenital or acquired PSS have higher protein requirements; long-term feeding of

#### FIG 39-1

**A**, A 9-year-old neutered female German Shepherd Dog with previously stable noncirrhotic portal hypertension treated medically for 8 years presented very depressed with a week-long history of anorexia (same dog as Fig. 38-12 in Chapter 38). **B** and **C**, In spite of immediate institution of tube feeding on admission, the dog rapidly developed fatal septic peritonitis as a result of rupture of an ulcer at the gastroduodenal junction. It was found that the dog had developed asymptomatic pyelonephritis. The referring veterinarian had recognized the hepatic encephalopathy but tried to manage it by starvation for a week which likely increased rather than decreased ammonia production through breakdown of muscle and also increased the risk of GI ulceration because of a lack of intraluminal gut nutrition.

a protein-restricted diet not only is not indicated but will result in protein-calorie malnutrition.

Whether it is due to congenital PSS in dogs and cats or acquired PSS (mainly in dogs), treatment of HE is much the same. The main difference is that acquired PSSs are usually the result of portal hypertension, so treatment of the other manifestations of this and the underlying liver disease will also be necessary in these cases (see the discussion of portal hypertension below). Recent studies in human medicine have questioned the actual efficacy of some of the treatment recommendations for HE, including lactulose. Controlled trials have not been conducted in animals to determine the optimal treatment for HE and for each stage (mild, moderate, severe) of HE; therefore current recommendations are based on studies in human medicine and on anecdotal reports in dogs and cats.

### Diet

The ideal diet for long-term management of HE is the same as the diet recommended in chronic liver disease in dogs; dietary recommendations are outlined in Table 38-2 and Box 39-1. Protein restriction has long been recommended in patients with HE owing to the fact that undigested protein

in the gut broken down by bacteria is a source of gut-derived ammonia. However, as has recently been pointed out, gut bacteria will metabolize only undigested protein that reaches the colon. This should not occur if the protein in the diet is very digestible and not in such excessive amounts that it overwhelms the digestive capacity of the small intestine. There are high amounts of ammonia in the portal circulation, particularly after a meal, but the main source of these is obligate catabolism of glutamine by small intestinal enterocytes as their main energy source, and intestinal glutaminase activity seems to increase for unknown reasons in humans with cirrhosis, increasing gut ammonia production. Studies in dogs with experimental PSS and animals and humans with acquired PSS have actually shown a higher protein requirement than in normal animals or people. Therefore the current recommendation is to feed animals with congenital or acquired PSS normal to only slightly reduced quantities of protein that is highly digestible and of high biological value in order to minimize the amounts of undigested protein reaching the colon and "wastage" of excess nonessential amino acids by transamination or deamination for energy. Some experts recommend that diets should have low amounts of aromatic amino acids, because these have

Long-term Medical Management of Hepatic Encephalopathy

#### **Dietary Management**

- Feed normal amounts (if possible) of high-quality, highly digestible protein to minimize the chance that any protein will reach the colon to be converted into NH3. Some veterinarians recommend increasing branched chain amino acids and reducing aromatic amino acids such as tryptophan, but there is no evidence that changing the dietary levels affects cerebrospinal fluid levels. Consider adding ornithine aspartate, which provides substrates for conversion of NH3 to urea (ornithine) and glutamine (aspartate). Restrict protein only if absolutely necessary to control neurologic signs
- Prevent protein-calorie malnutrition by avoiding prolonged fasting and/or excessive protein restriction because this will lead to hyperammonemia from breakdown of body protein
- Feed little and often to reduce the amount of liver work required and reduce the potential for undigested food to reach the colon.
- Fat: No special recommendations, although it should be fed in normal amounts and not restricted unless clinical steatorrhoea develops (rare). Avoid diets that are very high in fats, particularly with cholestasis or portal hypertension in which gastrointestinal signs may be exacerbated.
- Carbohydrates should be highly digestible as a primary calorie source, reducing the need for hepatic gluconeogenesis from fat and protein.
- Fermentable fiber reduces hepatic encephalopathy in the same way as lactulose. Nonfermentable fiber is also important because it prevents constipation and therefore reduces contact time for colonic bacteria to act on feces and produce ammonia.
- Zinc supplementation may reduce encephalopathy because zinc is used in many metalloenzymes in the urea cycle and in muscle metabolism of ammonia

#### Lactulose

Lactulose is a soluble fiber that acidifies colonic contents, reducing ammonia absorption, and also increases colonic bacterial cell growth, therefore incorporating ammonia in to bacterial cell walls. Cats should be given 2.5 to 5 ml PO q8h; dogs 2.5 to 15 ml PO q8h. Start at the low dose, and titrate to effect (2 to 3 soft stools a day).

#### **Antibiotics**

 Amoxicillin (22 mg/kg PO q12 h) or metronidazole (7.5 mg/kg PO q12h) to reduce gastrointestinal flora and also protect against bacteremia

Identify and Treat Concurrent Infections/Inflammation

been implicated in HE, but in fact there is no evidence that the ratio of dietary aromatic amino acid: branched chain amino acid has any effect on HE. Food should be fed in small amounts and often to avoid overwhelming the ability of the liver to metabolize it. Diets manufactured for dogs with liver disease are a good starting point (Hill's canine LD; Royal-Canin canine hepatic) but are rather protein-restricted, so they should be supplemented with a high-quality protein such as cottage cheese or chicken. An alternative is to feed a veterinary diet marketed for intestinal disease; these diets contain high-quality, highly digestible protein sources (Hill's canine or feline ID; Iam's canine or feline intestinal formula; Royal-Canin canine or feline digestive lowfat). Most, if not all, dogs with congenital or acquired PSS can tolerate normal protein concentrations if other measures are also implemented, as outlined in the subsequent paragraphs and in Box 39-1. A few require more marked restriction in the short term, but every effort should be made to increase to a normal protein concentration over the long term.

#### Lactulose

Lactulose (β-galactosidofructose) is a semisynthetic disaccharide that is not digestible by mammals and therefore passes into the colon, where it is degraded by bacteria into short chain fatty acids (SCFA), particularly lactic and acetic acid. These SCFAs help control signs of HE by acidification of the intestinal contents, which traps ammonium ions in the colon, and by promoting osmotic diarrhea. In addition, SCFAs are used as an energy source by colonic bacteria, allowing them to grow and thus incorporate colonic ammonia into their own bacterial protein, which is subsequently lost with the bacteria in the feces (a type of bacterial "ammonia trap").

The dose is adjusted until there are two to three soft stools per day (see Box 39-1); overdosing results in watery diarrhea. There are no known complications of chronic lactulose use in animals (other than diarrhea). However, the efficacy of lactulose has never been critically evaluated in dogs and cats with HE, and recent studies in humans suggest that it may not be as helpful as previously thought. Lactulose can also be given by enema in animals with acute HE (Box 39-2). Many cats and dogs object strongly to the sweet taste of lactulose; an attractive alternative is lactitol ( $\beta$ -galactosidosorbitol), which is a relative of lactulose and can be used as a powder (500 mg/kg/day in three to four doses, adjusted to produce two to three soft stools daily). Currently, lactitol is available in the United States as a food sweetener, but it has not been studied in dogs and cats with HE.

### **Antibiotic Treatment**

If dietary therapy alone or in combination with lactulose is insufficient to control signs of HE, other medications may be added. Antibacterial drugs that are effective for anaerobic organisms (metronidazole, 7.5 mg/kg administered PO q8-12h; amoxicillin, 22 mg/kg administered PO q12h) are preferable. Antibiotics effective for gram-negative, urca-splitting organisms (neomycin sulfate, 20 mg/kg administered PO q12h) may also be used, although neomycin is more useful

BOX 39-2

### Treatment of Acute Encephalopathic Crisis

- Remove/treat any identified precipitating cause.
- Nothing by mouth 24-48 hours; intravenous fluids.
- Avoid fluid overload (measure central venous pressure or monitor carefully clinically).
- Avoid/treat hypokalemia (triggers hepatic encephalopathy).
- Avoid/treat hypoglycemia (monitor blood glucose every 1 to 2 hours, particularly in small breeds in which hypoglycemia is common and can cause permanent cerebral damage).
- Monitor body temperature, and warm gently as necessary.
- Administer enemas to remove ammonia from colon: warm water, lactulose, or dilute vinegar.
- Instill a neomycin retention enema after the colon is clear and administer ampicillin intravenously.
- Treat any seizures:
  - Carefully rule out "treatable" causes (e.g., electrolyte imbalances, hypoglycemia, hypertension, idiopathic epilepsy).
  - Maintain other intensive care measures (as above).
  - Treat with an anticonvulsant:
    - Propofol boluses (1 mg/kg cats, 3.5 mg/kg dogs) followed by infusions (0.1 to 0.25 mg/kg/minute) usually most effective
    - Phenobarbital may also be used; diazepam of limited efficacy

in acute HE rather than in long-term use because intestinal bacteria tend to become resistant to neomycin. In addition, it is not systemically absorbed and remains within the gastrointestinal tract; it is preferable to use a systemically absorbed antibiotic over the long term to protect against bacteremia. The low dose of metronidazole is given to avert neurotoxicity as a potential adverse effect of delayed hepatic excretion. Other therapeutic strategies investigated in humans with chronic HE include ornithine aspartate supplementation (see Box 39-1) and probiotics to increase numbers of beneficial bacteria. These may show benefit in dogs in the future, but there are currently no published studies documenting their use in small animals.

### **Controlling Precipitating Factors**

Certain conditions are known to accentuate or precipitate HE and should be avoided or treated aggressively when detected (Box 39-3). In fact, in many cases it is the precipitating factors (rather than the diet) that are most important in triggering HE. It is particularly important to identify and treat any concurrent inflammatory disease because even infections as apparently mild as cystitis or middle ear disease can trigger HE episodes in susceptible individuals. Recent work in humans and experimental animals has highlighted the importance of inflammation and inflammatory cytokines in triggering HE (Wright et al., 2007).

BOX 39-3

Precipitating Factors for Hepatic Encephalopathy in a Susceptible Individual

#### Increased Generation of Ammonia in the Intestine

- A high-protein meal (e.g., puppy or kitten food)
- Very poorly digestible protein reaching the colon and allowing bacterial metabolism to ammonia
- Gastrointestinal bleeding (e.g., bleeding ulcer in acquired shunts with portal hypertension) or ingestion of blood
- Constipation (increases contact time between colonic bacteria and feces and therefore increases ammonia production)
- Azotemia (urea freely diffuses across colonic membrane and is split by bacteria to ammonia)

#### **Increased Generation of Ammonia Systemically**

- Transfusion of stored blood
- Catabolism/hypermetabolism/protein-calorie malnutrition (increases breakdown of lean body mass with release of NH<sub>3</sub>)
- Feeding a poor-quality protein (excessive deamination as protein is used for energy)

## Effects on the Uptake and Metabolism of Ammonia in the Brain

- Metabolic alkalosis (increases amount of unionized NH3 in circulation ,which increases passage across blood-brain barrier)
- Hypokalemia (results in alkalosis with consequences outlined above)
- Sedatives/anesthetics (direct interaction with various neurotransmitters)
- Estrus (may be due to production of neurosteroids with neurologic effects)
- Inflammation (inflammatory cytokines have been implicated in having a direct central effect)

#### ACUTE HEPATIC ENCEPHALOPATHY

#### **Treatment**

Acute HE is a true medical emergency. Fortunately, it is much less common than chronic, waxing and waning HE. Animals may present in seizure or comatose, and although HE initially causes no permanent brain damage, prolonged seizures, status epilepticus, or coma will; prolonged severe HE by itself may lead to serious cerebral edema as a result of accumulation of the osmolyte glutamine (from ammonia detoxification) in astrocytes. In addition, the effects of acute HE, particularly hypoglycemia, can be fatal if not recognized and treated. The treatment of acute encephalopathic crises is outlined in Box 39-2. Intensive management is required. However, treatment is worthwhile because some animals can go on to complete recovery and successful long-term medical management, particularly if the acute crisis was triggered by

CHAPTER 39

a definable event (e.g., acute gastrointestinal bleeding in a dog with chronic liver disease and portal hypertension). Nothing by mouth (NPO), administration of enemas, and intravenous fluid therapy constitute the basic therapeutic approach. Warm water cleansing enemas may be useful simply by removing colonic contents and preventing absorption of intestinal encephalotoxins. Lactulose or dilute vinegar may be added to acidify the colon and decrease absorption of ammonia. The most effective enema contains three parts lactulose to seven parts water at a total dose of 20 ml/kg. The solution is left in place, with the aid of a Foley catheter, as a retention enema for 15 to 20 minutes. For lactulose to be beneficial, the pH of the evacuated colon contents must be 6 or lower. These enemas can be given every 4 to 6 hours. Because lactulose is osmotically active, dehydration can occur if enemas are used too aggressively without careful attention to fluid intake. Fluids chosen for replacement of losses, volume expansion, and maintenance should not contain lactate, which is converted to bicarbonate, because alkalinizing solutions may precipitate or worsen HE by promoting formation of the more readily diffusible form of ammonia. Half-strength (0.45%) saline solution in 2.5% dextrose is a good empirical choice, with potassium added according to its serum concentration (see Table 55-1). Serum electrolyte concentrations in dogs with HE are extremely variable; until the results become available, 20 mEq KCl/L in administered fluids is a safe amount to add. Seizuring dogs can be stabilized with low-dose propofol infusions (Fig. 39-2) or phenobarbital. The dose of propofol is calculated by giving an initial bolus to effect (usually about 1mg/kg), timing how long it takes for the animal to show mild signs of seizuring, such as mild limb paddling again, and then dividing the dose by the time to calculate an infusion rate. For example, if after a bolus of 1 mg/kg of propofol the dog began to show signs of seizure activity again after 10 minutes, the infusion rate to give would be 1/10 = 0.1 mg/kg/min. In practice, the dose of propofol to give by constant rate infusion is usually about 0.1 to 0.2 mg/kg/min. Dogs sometimes need to remain on the infusion for hours or days, but the

FIG 39-2
A Miniature Schnauzer with a congenital portosystemic shunt that had postligation seizures is stabilized with a propofol infusion.

rate can be gradually reduced to control seizures while still allowing the dog to regain consciousness—in some cases, even enough to start eating.

In spite of some early promising reports, there is still no convincing evidence in support of other pharmacological treatments for HE, apart from antibiotics and lactulose, and therefore other drugs cannot currently be recommended for use in dogs. Trials of the benzodiazepine receptor antagonist flumazenil in human patients with refractory acute HE have had mixed results, and although flumazenil has been studied in animals for its ability to reverse the action of benzodiazepine tranquilizers, there have been no clinical studies on its use in acute HE in animals.

### **PORTAL HYPERTENSION**

### **Pathogenesis**

Portal hypertension is the sustained increase in blood pressure in the portal system and is seen most frequently in dogs with chronic liver disease, although it may also occasionally occur in dogs with acute liver disease. Portal hypertension is extremely uncommon in cats. It is caused by the increased resistance to blood flow through the sinusoids of the liver or (less commonly) by more direct obstructions to the portal vein such as thromboemboli. Early in chronic liver disease, portal hypertension can be the result of multiplication and phenotypic transformation of hepatic Ito (stellate) cells, which become contractile myofibroblasts that surround the sinusoids and cause constriction. In the longer term, fibrous tissue laid down by these transformed stellate cells results in more irreversible sinusoidal obstruction. The most common cause of portal hypertension is therefore chronic hepatitis progressing to cirrhosis in dogs (Fig. 39-3). It can also occur in association with hepatic neoplasia or diffuse hepatic swelling.

The changes in hemodynamics associated with "back pressure" in the portal circulation result in one or more of the typical triad of intestinal wall edema/ulceration, ascites, and acquired PSSs. Acquired PSSs occur as "escape valves" when the portal vein pressure is consistently higher than the pressure in the caudal vena cava (see Fig. 38-2). They are always multiple and occur as a result of the opening up of previously nonfunctional veloomental vessels. They are an important compensatory mechanism because they dissipate some of the increased portal pressure, limiting the increase in splanchnic pressure and thus reducing the risk of gastrointestinal ulceration. In humans with chronic portal hypertension, acquired PSSs have been demonstrated to prolong life expectancy by reducing the chance of serious gastrointestinal or esophageal bleeding—to the point that if they are not already present, they are often created surgically. Similar survival data are not available for dogs, but it is clear that ligation of acquired PSS is contraindicated and will result in fatal splanchnic congestion. Acquired PSSs result in HE in a similar way to congenital PSSs; treatment is outlined in the preceding section.

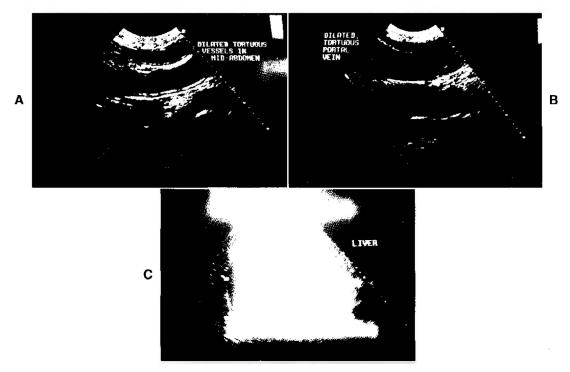

FIG 39-3

Ultrasonographic images demonstrating the progressive development of ascites with portal hypertension in a dog with cirrhosis: Ultrasonography on the first visit showed no evidence of free abdominal fluid, but dilated vessels in the midabdomen (including splenic congestion, A) and also a dilated portal vein (B). When the dog returned for a liver biopsy 2 weeks later, ultrasonography now revealed the development of mild early ascites (C). (Courtesy

Diagnostic Imaging Dept, Queen's Veterinary School Hospital, University of Cambridge.)

# SPLANCHNIC CONGESTION AND GASTROINTESTINAL ULCERATION

### **Pathogenesis**

Splanchnic congestion is a common and early complication of portal hypertension, the result of the pooling of blood in the splanchnic circulation and reduced flow into the portal system (see Fig. 39-3). This can cause visible congestion and edema of the gut wall that can be detected either ultrasonographically (where there may be thickening and loss of layering of the gut) or during surgery. It occurs before the onset of ascites and persists after ascites resolves (see Fig. 39-3). The congested gut wall is at increased risk of GI ulceration. Catastrophic gastrointestinal or esophageal ulceration is the most common cause of death in humans with portal hypertension who do not undergo a liver transplant, and it appears also to be the most common cause of death in dogs with stable chronic liver disease (see Fig. 39-1). Ulceration associated with portal hypertension in humans often takes the form of bleeding esophageal varices, whereas in dogs the ulceration is most commonly in the proximal duodenum, presumably reflecting a difference in the anatomy of the portal system in the two species. Preventing gastrointestinal ulceration is therefore vital, and for this reason it is very important to refrain from using ulcerogenic drugs (e.g., steroids) in dogs with portal hypertension whenever possible.

Corticosteroids have been shown to shorten the life expectancy of humans with chronic hepatitis and concurrent portal hypertension and should not be used in dogs with portal hypertension unless there is a very good reason for it. If they are deemed necessary, the owners should be fully informed of their potentially serious adverse effects. Other triggers for GI ulceration in dogs with portal hypertension are sepsis and protein-calorie malnutrition (discussed in more detail later), particularly if combined with a period of anorexia (see Fig. 39-1). The small intestine requires luminal glutamine and other nutrients to permit effective healing, and prolonged anorexia results in an increased risk of gastrointestinal ulceration as a result of glutamine depletion.

The clinician must be aware that GI ulceration may occur acutely in dogs with splanchic congestion and serious clinical deterioration may occur before melena is apparent because it takes several hours for the blood to pass from the small to the large intestine. Before this occurs, it is possible for the animal to show sudden onset and marked signs of HE because blood is a "high-protein meal" in the small intestine (see preceding section) or even for the ulcer to perforate and cause peritonitis (see Fig. 39-1).

### **Treatment**

Treatment of gastrointestinal ulceration largely revolves around its prevention (i.e., avoiding triggers as much as pos-

sible, such as the use of steroids or nonsteroidal antiinflammatory drugs, and avoiding hypotension during any surgery). It is particularly important that any dog with portal hypertension that undergoes a prolonged period of anorexia is fed because these individuals will be at high risk of gastrointestinal ulceration if they do not receive nourishment (see Fig. 39-1). Parenteral nutrition is not an effective alternative in these dogs because it does not supply luminal nutrients for enterocyte healing (in fact, upper gastrointestinal ulceration is a common adverse effect of total parenteral nutrition in humans, even in those without portal hypertension), and some form of enteral support should be instituted as soon as possible. The use of gastric acid secretory inhibitors (H2 blockers or proton pump inhibitors) is of questionable benefit in patients with portal hypertension because it is usually the duodenum that is ulcerated (rather than the stomach); also, there have been reports that the gastric pH in dogs with liver disease may already be higher than normal as a result of changes in gastrin metabolism. However, in the face of active ulceration and melena, they are often used in the hope that they will help. In these circumstances, cimetidine is contraindicated because of its effect on hepatic P450 enzymes; therefore ranitidine (2 mg/kg administered orally or via slow IV administration q12h) or famotidine (0.5 to 1 mg/kg administered PO q12-24h) are recommended. Likewise, sucralfate (Carafate<sup>TM</sup>.) is of questionable efficacy; it is most effective against gastric ulceration (i.e., in association with a low pH), but it is often used (at a dosage of 500 mg to 1 g per dog PO q8h). Hemostasis profiles should also be evaluated, and any coagulopathy treated with vitamin K (see the section on coagulopathy) or plasma transfusions.

### **ASCITES**

### **Pathogenesis**

The development of ascites (defined as the accumulation of a transudate or modified transudate in the peritoneal cavity) is another consequence of portal hypertension (see Fig. 39-3), but the pathogenesis is complex and has really been studied only in humans; it is assumed that the mechanisms of ascites are similar in dogs. One way in which dogs differ from humans is that dogs do not develop the "spontaneous" infection of ascites of liver origin by extension of gut bacteria into the fluid that results in peritonitis, which is commonly reported in people. The presence of ascites is a poor prognostic indicator in humans with chronic hepatitis, and the same appears to be true in dogs. Hypoalbuminemia contributes to the development of ascites but by itself is rarely sufficient to cause fluid accumulation; portal hypertension is a critical contributing factor. The development of ascites in patients with liver disease also seems to lead to sodium retention by the kidneys. In many cases there is systemic hypotension and increased renal sodium retention, partly as a result of reduced glomerular filtration rate and decreased sodium delivery to the tubules and partly as a result of increased release of renin-angiotensin-aldosterone (RAAS) that results in increased sodium retention in the distal

tubules. This leads to an increase in circulating fluid volume, precipitating the formation of ascites, which in turn reduces venous return because of increased pressure on the caudal vena cava and initiates a vicious cycle of renal sodium retention and ascites. Therefore aldosterone antagonists are usually most effective in dogs with ascites secondary to portal hypertension, whereas loop diuretics, such as furosemide used alone, can be ineffective or even, in some cases, actually increase the volume of effusion by causing a further decrease in systemic blood pressure as a result of hemoconcentration and secondary increases in RAAS activation.

#### **Treatment**

Treatment of ascites associated with liver failure revolves around the use of diuretics: first aldosterone antagonists (spironolactone, 1 to 2 mg/kg administered PO q12h), but then with the addition of furosemide (2-4 mg/kg administered PO q12h) if necessary in refractory cases. Spironolactone usually takes 2 or 3 days to reach full effect, and the resolution of ascites can be monitored by weighing the patient daily (any acute changes in weight will be due to fluid shifts). Dietary sodium restriction has also been recommended, although it is unclear how effective or important this is. However, it is certainly wise to refrain from feeding the patient high-salt snacks and treats.

It is very important to monitor serum electrolyte concentrations (mainly sodium and potassium) daily during the first few days of treatment and every few weeks to months thereafter, depending on how stable the dog and drug doses are. Hypokalemia should be avoided because it can precipitate HE (see preceding section), but it is less likely in a dog on both aldosterone antagonists and loop diuretics than in a dog on furosemide alone. Hyponatremia can also occur; if it is marked, the diuretics should be stopped and the patient given careful intravenous replacement until the sodium is normalized.

Therapeutic paracentesis is indicated only in patients with ascites that is severe enough to compromise breathing. This is actually unusual and is manifested by severe, drumlike ascites; the dog is unable to settle and lie down. Paracentesis should be accompanied by concurrent intravenous administration of a colloid plasma expander, plasma, or albumin; removal of a large volume of fluid containing albumin can result in a precipitous hypoalbuminemia and decrease in oncotic pressure, leading to pulmonary edema. This is a real problem in dogs with chronic liver disease in which the liver's capacity to manufacture albumin is reduced. Clear recommendations for dogs have not been published, but the recommendations for humans, adapted for dogs, are outlined in Box 39-4.

#### COAGULOPATHY

#### **Pathogenesis**

The liver plays a central role in both the coagulation and fibrinolytic systems. The liver synthesizes all the coagulation

BOX 39-4

Guidelines for Therapeutic Paracentesis in Dogs with Ascites Resulting from Liver Disease

Reserve for use ONLY in cases with severe, refractory ascites:

- Small volume paracentesis: follow up with intravenous plasma expansion with 2 to 5 ml/kg of gelofuscin or hemaccel
- Large volume paracentesis: volume expand preferably with albumin using 8 g albumin/l of ascites removed (i.e., 100 ml of 20% albumin per 3 liters of ascites).
   Failing that, use fresh frozen plasma (10 ml/kg slowly)

Adapted from Moore et al: Guidelines on the management of ascites in cirrhosis, *Gut* 55 (suppl 6):vi1, 2006.

factors with the exception of factor VIII and also makes the inhibitors of coagulation and fibrinolysis. Factors II, VII, IX, and X also require hepatic activation by a vitamin Kdependent carboxylation reaction. Hemostatic abnormalities are quite common in both dogs and cats with liver disease; in one study 50% and 75% of dogs with liver disease had prolongation of the one-stage prothrombin time (OSPT) and activated partial thromboplastin time (APTT), respectively (Badylak et al., 1983). In another study 82% of cats with liver disease had hemostatic abnormalities (Lisciandro et al., 1998). Cats appear to be particularly susceptible to prolongation of clotting times; this is at least partly due to reduced vitamin K absorption. Dogs and cats with vitamin K-responsive coagulopathies have prolongation of both the OSPT and APTT (and the OSPT may actually be longer than the APTT). Vitamin K is a fat-soluble vitamin, and its absorption is decreased in association with biliary tract disease (which is common in cats); bile acid secretion into the small intestine is also reduced. Moreover, the inflammatory bowel disease commonly seen concurrently in cats with chronic biliary tract disease results in reduced fat absorption. Finally, some cats with chronic biliary tract disease have concurrent chronic pancreatitis, and as this progresses to exocrine pancreatic insufficiency, fat absorption (and thus vitamin K absorption) will decline further.

In contrast, dogs with chronic liver disease rarely have clinically relevant prolongation of clotting times. However, in both species severe diffuse liver disease, particularly acute infiltration such as lipidosis (cats) and lymphoma (cats and dogs), will cause a decrease in the activity of clotting factors in many cases as a result of hepatocyte damage and reduced synthesis in the liver. In patients with lymphoma or lipidosis this decreased activity of clotting factors is rapidly reversible if the underlying disease can be successfully treated, thus allowing recovery of hepatocyte function. In one study of cats coagulopathies were seen most commonly in cats with hepatic lipidosis and cats with inflammatory bowel disease and concurrent cholangitis (Center et al., 2000).

Coagulopathies can also occur in dogs and cats with liver disease as a result of disseminated intravascular coagulation (DIC) with resultant prolongation of clotting times and thrombocytopenia. DIC is particularly a complication of acute, fulminating hepatitis and also some hepatic tumors; it carries a very poor prognosis.

### **Clinical Features and Diagnosis**

Despite the presence of hemostatic abnormalities, spontaneous bleeding is uncommon in patients with chronic liver disease but relatively common in those with acute disease. Because dogs with portal hypertension and gastrointestinal hemorrhage (see previous section) may also have a coagulopathy predisposing to their bleeding, they should be thoroughly evaluated. However, the risk of hemorrhage increases after a challenge to hemostasis, such as liver biopsy; therefore it is very important to evaluate hemostasis before performing liver biopsy. One study (Bigge et al., 2001) suggested that thrombocytopenia was a more significant predictor of bleeding complications after ultrasonography-guided biopsies in dogs and cats than prolongation of the OSPT and APTT. Therefore clinicians must perform a platelet count in dogs and cats before performing a liver biopsy. A platelet estimate can be can be done manually on the blood smear (Chapter 87) The platelet count (per  $\mu$ L) can be estimated by counting the number of platelets in 10 oil immersion fields and multiplying the average number per field by 15,000 to 20,000. Prolongation of coagulation times may also increase the risk of bleeding; in the same study, prolongation of the OSPT in dogs and the APTT in cats was significantly associated with bleeding complications after biopsy. Ideally, therefore, both OSPT and APTT should be evaluated in cats and dogs before hepatic biopsy; however, a practical alternative could be assessment of at least an activated clotting time (ACT) in a glass tube containing diatomaceous earth as a contact activator, although theoretically this is more useful in cats than dogs because it assesses the intrinsic pathway (=APTT) and final common pathway only.

Because factor depletion must be greater than 70% to result in prolongation of the OSPT or APTT, many more dogs and cats may have subtle abnormalities in the concentration of individual coagulation factors. These can be detected by more sensitive tests, such as measuring the concentration of individual clotting factors or the PIVKA (proteins induced by vitamin K absence) test, although its clinical efficacy in large numbers of dogs and cats is untested. If available, thromboelastography may allow for rapid quantification of hemostasis (see Chapter 87).

In dogs and cats with severe acute liver disease, spontaneous bleeding may result from depletion of clotting factors; in addition, there is a potential for developing DIC (see Chapter 87). In patients with DIC, APTT and OSPT may be prolonged, but it is impossible to distinguish this from reduced hepatic production of clotting factors. However, measurement of increased D-dimers and/or fibrin degradation products, combined with decreases in platelet count, increases the index of suspicion for DIC. D-dimer concen-

trations are often mildly to moderately increased in dogs with liver disease because of reduced clearance in the liver, and this does not necessarily mean that the dog has a thrombus or DIC. More marked elevations are suggestive of DIC.

#### **Treatment**

Dogs and cats with prolonged clotting times associated with chronic liver disease often respond to parenteral vitamin K supplementation alone. It is recommended that all patients receive vitamin K1 (phytomenadione), at a dosage of 0.5 to 2.0 mg/kg administered IM or SQ 12 hours before biopsy and repeated q12h for 3 days as necessary.

It is important to monitor clotting during long-term therapy (OSPT + APTT or PIVKA) and stop when they normalize because it is possible to overdose on vitamin K, which can result in Heinz body hemolysis. If the coagulopathy fails to respond to vitamin K treatment alone or if there are clinical signs of hemorrhage associated with the disease (which is more common with acute disease), administration of fresh frozen plasma or stored plasma is indicated to replenish depleted clotting factors. A starting dose of 10 ml/kg given slowly is recommended; the dose of plasma is titrated on the basis of the results of the OSPT and APTT. Again, liver biopsy, surgery or the placement of central venous catheters should not be contemplated until coagulation times have been normalized.

The treatment of DIC is difficult and frequently unsuccessful. The most effective treatment is to remove the inciting cause, which in acute liver failure in humans means rapid liver transplant. Without this option in dogs and cats, the mortality in DIC of acute fulminant hepatitis is likely to be 100%. Recommended therapies include plasma transfusion to replace depleted clotting factors and careful heparin therapy during the hypercoagulable phase. However, the efficacy of heparin therapy in DIC has recently been called into question in humans, and there are no clinical data supporting its use in dogs and cats.

### PROTEIN-CALORIE MALNUTRITION

### **Pathogenesis**

Protein-caloric malnutrition is very common in dogs with chronic hepatitis as a result of reduced intake caused by anorexia, vomiting, and diarrhea and increased loss/wastage of calories caused by hypermetabolism and poor liver function. Protein-caloric malnutrition is likely to have a serious impact on both longevity and quality of life in affected dogs. There are no studies specifically addressing the effect of malnutrition on survival and infections of dogs with liver disease, but in other canine diseases it is known to increase the risk of septic complications. This is true in humans with portal hypertension and also likely in dogs. In humans with portal hypertension malnutrition also predisposes to gut ulceration. In addition, negative nitrogen balance and reduced muscle mass predispose to HE. Breakdown of body protein results in more ammonia production, and also in a normal

individual up to 50% of arterial ammonia is metabolized in skeletal muscle by conversion of glutamate to glutamine, so loss of muscle mass will reduce the ability to detoxify ammonia. What gives the most cause for concern regarding protein-calorie malnutrition in the veterinary patient is that it is often partly caused by well-meaning but unhelpful manipulations by the clinician or even by a lack of recognition and attention (discussed in greater detail later). For this reason, it is very important that clinicians treating dogs with chronic liver disease remain alert to the possibility of protein-calorie malnutrition.

Malnutrition can also be seen in dogs and cats with congenital PSS, both as a result of reduced liver synthetic capability or as a result of inappropriately severe protein restriction by the attending clinician. Cats with chronic liver disease may have negative energy balance, often as a result of the effects of concurrent intestinal and pancreatic disease reducing digestion and absorption of food. In addition, cats in negative nitrogen balance are at a particular risk of developing acute hepatic lipidosis (see Chapter 37) so protein-calorie malnutrition in this species requires particularly aggressive management.

### **Clinical Signs and Diagnosis**

When suffering from severe malnutrition, dogs and cats appear cachectic, with reduced muscle mass. However, loss of muscle mass occurs relatively late in the process, and in the earlier stages of protein-calorie malnutrition the animal's body condition score may be normal and yet many potentially deleterious effects on the immune system and gut wall will already be under way. There is no simple blood test that allows diagnosis of malnutrition. The most effective means to do this is by taking a careful history as well as performing a clinical examination. Any animal with liver disease should be considered as being at risk of protein-calorie malnutrition. A history of partial or complete anorexia for more than 3 days or recent weight loss of >10% not associated with fluid shifts should trigger rapid and aggressive nutritional management.

### **Treatment**

The treatment is to feed the patient an appropriate diet. Protein restriction should be avoided as much as possible—and in some cases of chronic liver disease associated with obvious cachexia, supplementation of a maintenance diet with extra high-quality protein (such as dairy protein) is even indicated. If the patient will not eat voluntarily, some form of assisted tube feeding should be instituted short term. This is particularly important in cats with hepatic lipidosis, which almost invariably refuse to eat independently and require gastrostomy or esophagostomy tube feeding (see Chapter 37). A search should then be made for any underlying cause of anorexia, such as concurrent infections (see Fig. 39-1).

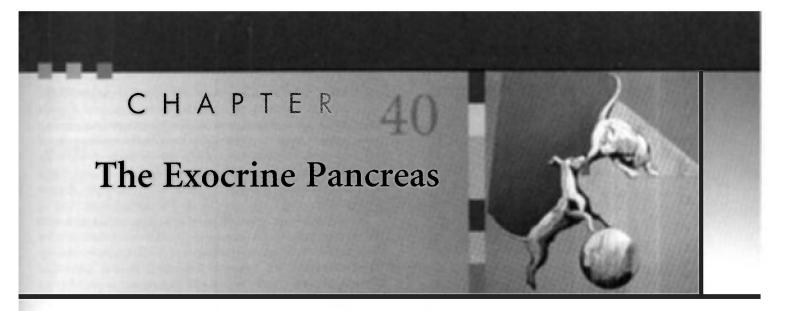

It is very important to avoid iatrogenic malnutrition while the patient is hospitalized. Withholding food for several days to allow multiple tests (e.g., liver biopsy or endoscopy) is a common problem; tests should be spread out over a

longer period if necessary to allow feeding between them. It is also possible for malnutrition to develop unnoticed in the hospital as a result of inadequate record keeping and frequent staff turnover. Finally, feeding an excessively protein-restricted diet to a dog or cat with liver disease can also result in negative nitrogen balance.

### CHAPTER OUTLINE

GENERAL CONSIDERATIONS PANCREATITIS

Acute Pancreatitis
Chronic Pancreatitis
EXOCRINE PANCREATIC INSUFFICIENCY
EXOCRINE PANCREATIC NEOPLASIA
PANCREATIC ABSCESSES, CYSTS, AND
PSEUDOCYSTS

### **GENERAL CONSIDERATIONS**

The pancreas is located in the cranial abdomen, with the left limb positioned between the transverse colon and the greater curvature of the stomach and the right limb running alongside the proximal duodenum. Any or all of these neighboring structures can be affected when there is pancreatic inflammation. The exocrine acini make up about 90% of pancreatic tissue, and the endocrine islets interspersed among the acini make up the other 10% (Fig. 40-1). The close anatomical association between the acini and islets allows subtle signaling between them to coordinate digestion and metabolism, but it also means that there is a complex cause-and-effect relationship between diabetes mellitus and pancreatitis. The major function of the exocrine pancreas is to secrete digestive enzymes, bicarbonate, and intrinsic factor (IF) into the proximal duodenum. Pancreatic enzymes are responsible for the initial digestion of larger food molecules and require an alkaline pH to function (hence the concurrent bicarbonate secretion by pancreatic duct cells). The pancreas secretes several proteases, phospholipases, ribonucleases, and deoxyribonucleases as inactive precursors (zymogens) and also -amylase and lipase as intact molecules. The pancreas is the only significant source of lipase, and hence steatorrhea (fatty feces) is a prominent sign of exocrine pancreatic insufficiency (EPI). Trypsin is central to the pathogenesis of pancreatitis, as outlined in the subsequent sections, and

inappropriate early activation of the zymogen trypsinogen to trypsin within the pancreatic acini is the final common pathway triggering pancreatic inflammation. In the normal animal pancreatic secretion is triggered by the thought of food and stomach filling and most potently by the presence of fat and protein in the small intestinal lumen. The vagus nerve, the local enteric nervous system, and the hormones secretin and cholecystokin from the small intestine all stimulate pancreatic secretion. Trypsinogen is activated within the small intestine by the brush border enzyme enterokinase, which cleaves a peptide (the "trypsin-activation peptide" [TAP]) from trypsinogen. Activated trypsin then activates the other zymogens within the intestinal lumen. IF, which is necessary for vitamin B<sub>12</sub> absorption in the ileum, is secreted only by the pancreas in the cat. In the dog the pancreas is the main source of IF, but a small amount is also secreted by the gastric mucosa.

Diseases of the exocrine pancreas are relatively common but often misdiagnosed in both dogs and cats because of nonspecific clinical signs and a lack of sensitive and specific clincopathological tests. Pancreatitis is the most common disease of the exocrine pancreas in both cats and dogs; EPI, although less common, is also recognized frequently. Uncommon diseases of the pancreas include pancreatic abscess, pseudocyst, and neoplasia.

Recent advances in the understanding of the pathophysiology, prevalence, and potential causes of pancreatitis in dogs and cats may give clues to treatment in the future, although treatment of acute pancreatitis remains largely nonspecific and supportive in all species.

Important differences in the anatomy of the pancreas and associated areas between the dog and cat are outlined in Table 40-1.

### **PANCREATITIS**

Pancreatitis may be acute or chronic. As with acute and chronic hepatitis, the difference is histological and not necessarily clinical (Table 40-2 and Fig. 40-2), and there is some clinical overlap between the two. Chronic disease may present

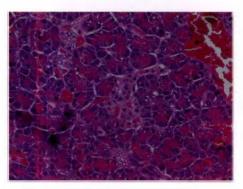

FIG 40-1
Histopathology of a section of normal canine pancreas showing two paler staining islets of Langerhans and exocrine acini surrounding them. Note that the islets make up only 10% to 20% of the volume of the pancreas.

initially as an acute-on-chronic episode; in postmortem studies of fatal acute pancreatitis in dogs and cats, up to half of the cases were actually acute-on-chronic disease. Differentiation of truly acute disease from an acute flare-up of chronic disease is not important for initial management, which is the same in all cases, but is important to allow recognition of the potential long-term sequelae of chronic disease, as outlined in the following sections. The causes of acute and chronic pancreatitis may be different, but there may also be some overlap between them.

### **ACUTE PANCREATITIS**

### **Etiology and Pathogenesis**

Understanding of the pathophysiology of acute pancreatitis in humans has increased in recent years with the discovery of hereditary mutations of trypsin, which predispose to pancreatitis; the pathophysiology of this disease is believed to be similar in dogs and cats. The final common pathway in all cases is the inappropriate early activation of trypsinogen within the pancreas as a result of increased autoactivation and/or reduced autolysis. Trypsin is the major protease secreted by the pancreas, and inappropriate early activation within the acinar cells would obviously cause autodigestion and severe inflammation. Protective mechanisms therefore exist to prevent early activation: Trypsin is stored within zymogen granules in the pancreatic acini as the inactive precursor trypsinogen; up to 10% of trypsinogen gradually autoactivates within the granules but is inactivated by the action of other trypsin molecules and by the co-segregating protective molecule pancreatic secretory trypsin-inhibitor (PSTI; also known as serine protease inhibitor Kazal type 1, or SPINK1). Genetic mutations of trypsinogen, which make it resistant to hydrolysis, and/or of PSTI predispose to pancreatitis in people and are also likely to occur in some dogs (Table 40-3). If too much trypsin autoactivates within the pancreas, the protective mechanisms are overwhelmed and a chain reaction occurs, whereby activated trypsin activates more trypsin and the other enzymes within the pancreas, with the resulting pancreatic autodigestion, inflammation, and peripancreatic fat necrosis that leads to focal or more generalized sterile peritonitis. There is an associated systemic inflammatory response (SIR) in even the mildest cases of pancreatitis. Many other organs may be involved, and in the most severe cases, there is multiorgan failure and diffuse intravascular coagulation (DIC). The circulating protease inhibitors  $\alpha_l$ -antitrypsin (=  $\alpha_l$ -protease inhibitor) and  $\alpha$ -macroglobulin play a role in removing trypsin and other proteases from the circulation. Saturation of these protease inhibitors by excessive amounts of circulating proteases contributes to the systemic inflammation, but generalized neutrophil activation and cytokine release is probably the primary cause of SIR.

The previous paragraph describes the final common pathway of acute pancreatitis in dogs and cats, but the underlying cause of the disease is often unknown (see Table 40-3). There appears to be a strong breed relationship in dogs with pancreatitis, so hereditary causes are likely to be a factor in this species. Many of the previously reported supposed causes in dogs are likely triggers for disease in genetically susceptible individuals.

#### **Clinical Features**

Acute pancreatitis typically affects middle-aged dogs and cats, although very young and very old individuals may also be affected. Terrier breeds, Miniature Schauzers, and domestic short-haired cats appear to be at increased risk for acute pancreatitis, although any breed or cross-breed can be affected. Some dog breeds appear to be underrepresented in clinical studies, particularly large and giant breeds, although Labrador Retrievers are sometimes affected and also sometimes Husky-types (particularly in Australia). Breed relationships suggest an underlying genetic tendency, mirroring the situation in humans. It is likely that the disease is multifactorial with a genetic tendency and superimposed triggering factors. For example, eating a high-fat meal may be a trigger for a susceptible terrier. Some studies suggest a slight increase in risk in female dogs, whereas others show no sex predisposition. Obesity has been suggested as a predisposing factor in dogs, but it is unclear whether this is a cause or whether it is co-segregating with disease (i.e., breeds at high risk for acute pancreatitis may coincidentally also be breeds with a high risk for obesity). In cats there is a recognized association with concurrent cholangitis, inflammatory bowel disease, or renal disease in some cases. Cats with acute pancreatitis are also at high risk for hepatic lipidosis.

The history in dogs often includes a trigger such as a high-fat meal or engorging (see Table 40-3). Recent drug therapy may also be a trigger, particularly potassium bromide, azathioprine or asparaginase in dogs. Concurrent endocrine diseases such as hypothyroidism, hyperadrenocorticism, or diabetes mellitus (DM) increase the risk of severe fatal pancreatitis in dogs; therefore it is important to identify these in the history. In cats the history may include features of concurrent cholangiohepatitis, inflammatory bowel disease, or hepatic lipidosis (or any combination thereof).

TABLE 40-1

Differences in Pancreatic Structure, Function, and Diseases Between Dogs and Cats

FEATURE	DOGS	CATS
Anatomy	Usually two pancreatic ducts:	Usually single major pancreatic duct joining the
(but many variations; some dogs are like	large accessory duct from right limb to minor papilla in duodenum	common bile duct before entering duodenum at duodenal papilla 3 cm distal to pylorus
cats and vice versa)	small pancreatic duct from left limb to major duodenal papilla in duodenum beside (but not joining) bile duct	20% of cats have second, accessory duct; occasionally ducts remain separate Sphincter of Oddi may be as important as in
	Sphincter of Oddi unlikely to be of clinical significance	humans
Pancreatic function	Intrinsic factor secreted largely by pancreas but also some in stomach; vitamin B <sub>12</sub> deficiency common in exocrine insufficiency but sometimes normal	Intrinsic factor secreted entirely by pancreas so Vitamin B <sub>12</sub> deficiency very common in exocrine insufficiency; vitamin K deficiency also common because of concurrent liver and intestinal disease further reducing absorption
Pancreatitis: disease associations	Common association between pancreatitis and endocrine disease (see text)	Common association with cholangiohepatitis and/or inflammatory bowel disease
	Association with liver and small intestinal disease not recognized	High risk concurrent hepatic lipidosis May also be associated with renal disease
	Emerging association in some breeds with immune-mediated diseases, particularly keratoconjunctivitis sicca (see text)	may also be associated with retial disease
Exocrine pancreas: other pathology	Incidental pancreatic nodular hyperplasia common	Incidental pancreatic nodular hyperplasia common
. •	Cystic acinar degeneration rare	Cystic acinar degeneration common and associated with chronic pancreatitis
Pancreatitis: spectrum of disease	Most cases acute at presentation Low-grade chronic disease increasingly	Most cases low-grade, chronic interstitial, and a challenge to diagnose
	recognized and more common than acute on postmortem studies	Acute severe cases also recognized
Pancreatitis: diagnosis	Histology gold standard	Histology gold standard
· ·	Variety of catalytic and immunoassays available	Catalytic assays no help Immunoassays more helpful
	Ultrasonography quite sensitive	Ultrasonography less sensitive than in dogs
	Obvious/suggestive clinical signs in acute cases	Clinical signs usually low-grade and nonspecific even in acute disease
Causes of exocrine pancreatic insufficiency	Often pancreatic acinar atrophy— increased prevalence in certain breeds (especially German Shepherd Dogs)	Most cases end-stage chronic pancreatitis Pancreatic acinar atrophy not reported
,	End-stage chronic pancreatitis also common and under-recognized, particularly middle-aged to older dogs of specific breeds (see text)	

The clinical signs in dogs vary with the severity of the disease from mild abdominal pain and anorexia at one end of the spectrum to an "acute abdomen" and potential multiorgan failure and DIC at the severe end of the spectrum. Dogs with severe acute disease usually present with acute vomiting, anorexia, marked abdominal pain, and varying degrees of dehydration, collapse, and shock. The vomiting is initially typical of delayed gastric emptying resulting from peritonitis, with emesis of undigested food a long time after feeding progressing to vomiting only bile. The main differential diagnoses in these cases are other

causes of acute abdomen, particularly intestinal foreign body or obstruction; the vomiting may be so severe that the dog may undergo an unnecessary laparotomy for a suspected obstruction if a careful workup was not performed first. Some patients may show the classic "praying stance," with the forelegs on the floor and the hindlegs standing (Fig. 40-3), but this is not pathognomonic for pancreatitis and can be seen in association with any pain in the cranial abdomen, including hepatic, gastric, or duodenal pain. By contrast, cats with severe, fatal, necrotizing pancreatitis usually have surprisingly mild clinical signs, such as anorexia

**TABLE 40-2** 

### Differences Between Acute and Chronic Pancreatitis in Dogs and Cats

	ACUTE PANCREATITIS	CHRONIC PANCREATITIS
Histopathology	Varying degrees of acinar necrosis, edema, and inflammation with neutrophils and peri-pancreatic fat necrosis	Characterized by lymphocytic inflammation and fibrosis with permanent disruption of architecture
	Potentially completely reversible with no permanent pancreatic architectural or functional changes	Possible to have acute-on-chronic cases with concurrent neutrophilic inflammation and necrosis
Clinical appearance	Spectrum from severe and fatal (usually necrotizing) to mild and subclinical (less common)	Spectrum from mild, low-grade intermittent gastrointestinal signs (most common) to an acute-on-chronic episode indistinguishable from classical acute pancreatitis
Diagnostic challenge	Higher sensitivity of enzyme tests and ultrasonography than in chronic disease	Lower sensitivity of enzyme tests and ultrasonography than in acute disease: diagnosis much more challenging
Mortality and long- term sequelae	High immediate mortality but no long-term sequelae	Low mortality except acute-on-chronic bouts High risk of eventual exocrine and endocrine insufficiency

TABLE 40-3

### Causes of Acute Pancreatitis in Dogs and Cats

RISK FACTOR	CAUSE
Idiopathic 90%	Unknown (some may be hereditary)
Duct obstruction ± hypersecretion ± bile reflux into pancreatic duct	Experimental; neoplasia; surgery ± cholangitis + role in chronic pancreatitis
Hypertriglyceridemia	Inherent abnormal lipid metabolism (breed related, e.g., Min. Schnauzers)
	Endocrine: diabetes mellitus, hyperadrenocortism, hypothyroidism
Breed/sex?	Increased risk terriers ± spayed females—may reflect risk of
	hypertriglyceridemia (also Min. Schnauzers; see above)
Diet	Dietary indiscretion/high-fat diet
	Malnutrition; Obesity?
Trauma	Road traffic accident, surgery, "high rise syndrome"
Ischemia/reperfusion	Surgery (not just pancreas), gastric dilatation and volvulus; shock, severe immune-mediated hemolytic anemia (common association if anemia severe)
Hypercalcemia	Experimental; hypercalcemia of malignancy (uncommon association clinically); primary hyperparathyroidism
Drugs/toxins	Organophosphates; azathioprine; asparaginase; thiazides; furosemide; estrogens; sulpha drugs; tetracycline; procainamide, potassium bromide.
Infections	Toxoplasma, others (uncommon)

From Villiers E, Blackwood L, editors: BSAVA manual of canine and feline clinical pathology, ed 2, Gloucestershire, United Kingdom, 2005, British Small Animal Veterinary Association.

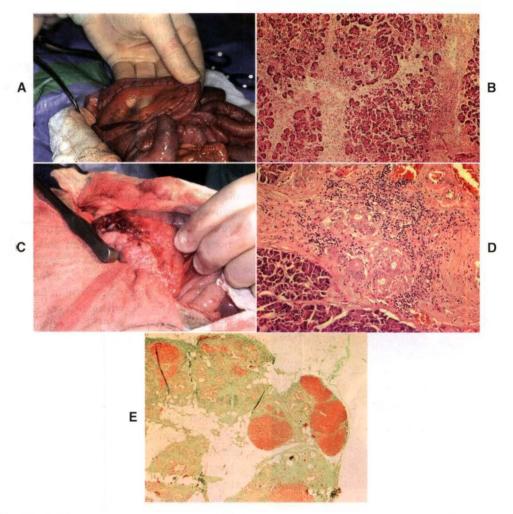

and lethargy; vomiting and abdominal pain occur in fewer than half the cases.

At the milder end of the spectrum, dogs and cats may present with mild gastrointestinal signs—typically anorexia and sometimes some mild vomiting, followed by the passage of some colitic-like feces accompanied by some fresh blood resulting from local peritonitis in the area of the transverse colon. Inflammatory bowel disease, low-grade infectious enteritis, and chronic hepatitis would be major differential diagno-

ses for this presentation in dogs as well as cats. Animals that are still eating may show prominent postprandial discomfort.

Both cats and dogs with acute pancreatitis can present with jaundice, either at initial examination or often developing a few days later, when the initial acute signs are resolving. In fact, most, if not all, animals with jaundice have acute-onchronic disease (see the section on chronic pancreatitis).

Careful clinical examination should focus on identification of the degree of dehydration and shock, careful assess-

#### FIG 40-2

A, Gross appearance of acute pancreatitis in a cat at laparotomy demonstrating generalized hyperemia. It is also possible for acute pancreatitis to appear normal grossly. B, Histopathological appearance of acute pancreatitis in a young adult female West Highland White Terrier. Note prominent edema and inflammation disrupting the acini. This case was fatal, but it would have been potentially completely reversible if the dog had survived the acute phase. Hematoxylin and eosin ×100. C, Gross appearance of chronic pancreatitis in a middle-aged Jack Russell Terrier. Note nodular appearance of pancreas and extensive adhesions to the duodenum obscuring the mesentery. It is also possible for chronic pancreatitis to appear normal grossly. D, Histological appearance of chronic pancreatitis from a 10-year-old male Cavalier King Charles Spaniel. Note fibrosis, mononuclear inflammatory cells, and ductular hyperplasia. Hematoxylin and eosin ×200. E, Histological appearance of end-stage chronic pancreatitis in an 11-year-old neutered female Cavalier King Charles Spaniel with diabetes mellitus and exocrine pancreatic insufficiency. Note extensive fibrosis (green) and small islands of remaining acini (red). Massons Trichrome ×40. (A and C, From Villiers E, Blackwood L, editors: BSAVA manual of canine and feline clinical pathology, ed 2, Gloucestershire, United Kingdom, 2005, British Small Animal Veterinary Association.)

ment for any concurrent diseases (particularly endocrine disease), and careful abdominal palpation. In severe cases petechiae or ecchymoses suggestive of DIC may be identified, and there may be respiratory distress associated with acute respiratory distress syndrome. Careful clinical and clinicopathological assessment of the degree of shock and concurrent organ damage is important for prognosis

and treatment decisions, as outlined in the following sections. Abdominal palpation should identify pancreatic pain and rule out, if possible, any palpable foreign bodies or intussusceptions, although abdominal imaging will be required to rule these out with confidence. In severe cases generalized peritonitis will result in generalized unmistakable abdominal pain, whereas in milder cases careful palpation of the cranial

abdomen is required to identify a focus of abdominal pain, as indicated in Fig. 40-4. Occasionally, a cranial abdominal mass may be palpated, particularly in cats, representing a focus of fat necrosis.

### **Diagnosis**

### **Routine Clinical Pathology**

Routine laboratory analysis (i.e., complete blood count [CBC], serum biochemical profile, and urinalysis) typically does not help in arriving at a specific diagnosis, but it is very important to perform these in all but the mildest cases because they give important prognostic information and aid in effective treatment, as outlined in the following sections.

PIG 40-3
Dog exhibiting evidence of cranial abdominal pain by assuming the "position of relief." (Courtesy Dr. William E. Hornbuckle, Cornell University, College of Veterinary Medicine.)

Typical clinicopathologic abnormalities in dogs and cats with acute pancreatitis are shown in Table 40-4.

### **More Specific Pancreatic Enzyme Assays**

More specific laboratory tests for the pancreas are the catalytic assays amylase and lipase and the immunoassays trypsinlike immunoreactivity (TLI) and pancreatic lipase immunoreactivity (PLI). Catalytic assays rely on the ability of the molecule to catalyze a reaction in vivo and thus rely on presence of active enzyme; however, they are not species specific. In cats amylase and lipase are of very questionable diagnostic value. Immunoassays, however, use an antibody against a part of the enzyme molecule distant from the active site and thus will also measure inactive precursors (e.g., trypsinogen) and tend to be organ and species specific. The advantages and disadvantages of the different assays are outlined in Table 40-5. Overall, PLI has the highest sensitivity and likely the highest specificity in both species and is the only reliable test for pancreatitis currently available in cats. A SNAP® test for canine PLI has recently been released by IDEXX (see details at http://www.idexx.com/animalhealth/ testkits/snapcpl/index.jsp), which should aid in rapid diagnosis.

### **Diagnostic Imaging**

The most sensitive way to image the canine and feline pancreas noninvasively is by ultrasonography. Abdominal radiographs in patients with pancreatitis usually show mild or no changes, even in those with severe disease (Fig. 40-5). However, in patients with acute disease, abdominal radiography plays an important role in ruling out acute intestinal obstruction, which would result in obvious changes, primarily dilated, gas-filled, stacking loops of intestine. Classical radiographic changes in dogs and cats with acute pancreatitis include focal decrease in contrast in the cranial abdomen

FIG 40-4

Carefully palpating a Cocker Spaniel for cranial abdominal pain. **A,** The clinician should palpate craniodorsally under the rib cage for evidence of focal pancreatic pain (as shown in this dog by turning of the head). **B,** With deep-chested dogs it helps to ask an assistant to elevate the head of the dog to displace the pancreas caudally (effectively achieving the opposite of the dog in Fig. 40-3).

**TABLE 40-4** 

### Typical Clinicopathologic Findings in Dogs and Cats with Acute Pancreatitis

PARAMETER	CHANGES IN DOGS	CHANGES IN CATS	CAUSE AND SIGNIFICANCE
Urea +/- creatinine	Increased in 50% to 65% of cases	Urea increased in 57% of cases and creatinine in 33%	Usually prerenal because of dehydration and hypotension (urea > creatinine) and indicates need for aggressive fluid therapy Often also some intrinsic renal failure (sepsis and
Potassium	Decreased in 20% of cases	Decreased in 56% of cases	immune-complexes) Increased loss in vomiting and renal loss with fluid therapy + reduced intake and aldosterone release caused by hypovolemia Requires treatment because contributes to gastrointestinal atony
Sodium	Can be increased (12%), decreased (33%), or normal	Usually normal or decreased (23%) Increased only in 4% of cases	Increase caused by dehydration; decrease caused by loss in gastrointestinal secretions with vomiting
Chloride	Very commonly decreased (81%)	Unknown	Loss in gastrointestinal secretions with vomiting
Calcium	Increased in about 9% of cases and decreased in about 3% of cases	Total calcium reduced in 40% to 45% of cases; ionized calcium reduced in 60% of cases; total calcium increased in 5%	Reduction poor prognostic indicator in cats but of no prognostic significance in dogs; caused by saponification in peripancreatic fat (unproven) and glucagon release stimulating calcitonin in some. Increased calcium likely cause rather than effect of disease
Phosphate	Often increased (55%)	Increased in 27%, decreased in 14%	Increase usually due to reduced renal excretion secondary to renal compromise; decrease (in cats) due to treatment for diabetes mellitus
Glucose	Increased in 30% to 88%, decreased in up to 40%	Increased in 64%, very rarely decreased	Increased because of decreased insulin and increased glucagon, cortisol, and catecholamines; about half return to normal; decreases caused by sepsis and anorexia
Albumin	Increased in 39% to 50%, reduced in 17%	Increased in 8% to 30%, reduced in 24%	Increase due to dehydration; decrease due to gut loss, malnutrition, concurrent liver disease, or renal loss
Hepatocellular enzymes (ALT and AST)	Increased in 61%	Increased in 68%	Hepatic necrosis and vacuolation due to sepsis, local effects of pancreatic enzymes +/- concurrent hepatic disease in cats
Cholestatic enzymes (ALP and GGT)	Increased in 79%	Increased in 50%	Biliary obstruction due to acute-on-chronic pancreatitis +/- concurrent cholangitis +/- lipidosis in cats; steroid induced ALP in dogs
Bilirubin	Increased in 53%	Increased in 64%	As GGT
Cholesterol	Increased in 48% to 80%	Increased in 64%	Can be due to cholestasis; unclear in others if cause or effect: often due to concurrent/ predisposing disease
Triglycerides	Commonly increased	Rarely measured	Unclear if cause or effect: often due to concurrent/ predisposing disease
Neutrophils	Increased in 55% to 60%	Increased in about 30%, decreased in 15%	Increase due to inflammatory response; decrease in some cats due to consumption—may be poor prognostic indicator
Hematocrit	Increased in about 20% and decreased in about 20%	As dogs	Increase due to dehydration; decrease due to anemia of chronic disease; gastrointestinal ulceration
Platelets	Commonly decreased in severe cases (59%)	Usually normal	Decrease due to circulating proteases +/- disseminated intravascular coagulation

**TABLE 40-5** 

The Use of Specific Catalytic Enzyme Tests and Immunoassays in the Diagnosis of Acute and Chronic Pancreatitis in Dogs and Cats

ASSAY	ADVANTAGES	DISADVANTAGES
Catalytic assays Dogs only—of no use in cats		Either may be normal in severe ± chronic pancreatitis due to enzyme depletion ± loss of tissue; degree of elevation of no prognostic value, except where stated; both renally excreted and elevated 2 or 3 times in azotemia
Amylase	Widely available on in-house analyzers Steroids do not elevate it so can help diagnose pancreatitis in dog with hyperadrenocorticism	Low sensitivity and specificity because of high background level from other sources, including small intestine
Lipase	Widely available on practice analyzers; more sensitive than amylase; degree of elevation may have prognostic significance	Extrapancreatic sources so high background level. Steroids elevate up to 5×.
Immunoassays		
Canine TLI •	Elevations high specificity for pancreatitis	Low sensitivity for diagnosis of pancreatitis (but high sensitivity for EPI); said to rise and fall more quickly than lipase or amylase; renally excreted: elevated 2 or 3 times in azotemia May be inappropriately low in severe ± chronic cases
		due to pancreatic depletion ± loss of tissue mass; no clear prognostic significance
Feline TLI	One of only two assays available for cats	Lower sensitivity and specificity than canine TLI—better used for diagnosis of EPI; renally excreted so elevated in azotemia
Canine PLI	Early indications most sensitive and specific test for canine pancreatitis; organ specific, so no interference from extrapancreatic sources  Now available as in-house test	Increased in renal disease but may not be significantly so? (Unclear yet if affected by steroids)
	(see URL in text)	
Feline PLI	Very new test but appears most sensitive and specific test available for feline pancreatitis	Very little published data available on its use

TU, Trypsinlike immunoreactivity; PU, pancreatic lipase immunoreactivity

associated with local peritonitis; a dilated, fixed (C-shaped), and laterally displaced proximal duodenum on ventrodorsal views; and caudal displacement of the transverse colon. Occasionally, a "mass" effect may be seen in the region of the pancreas, usually the result of fat necrosis. Pancreatic tumors by contrast are usually small, but it is impossible to differentiate fat necrosis from neoplasia using imaging alone. Abdominal radiographs appear normal in many dogs and cats with acute or chronic pancreatitis. Barium studies should be avoided, if possible, because they do not contribute to diagnosis and the associated gut filling provides further stimulus for pancreatic enzyme release.

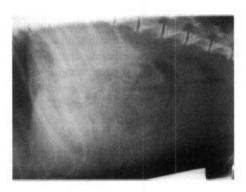

The most sensitive imaging modalities in humans with pancreatitis are magnetic resonance imaging (MRI), computed tomography (CT), or transendoscopic ultrasonography. CT has so far proved disappointing in both cats and

dogs. Pancreatic MRI has not been reported in small animal species, and transendoscopic ultrasonography is not widely available, although it would be expected to be useful insofar as the pancreas can be imaged very closely from the adjacent stomach or duodenum. Because all these techniques require general anesthesia, they may never become widely used in small animal patients with severe acute pancreatitis. Transcutaneous ultrasonography has a high specificity for pancreatic disease (i.e., if a lesion is found, it is real) but a variable sensitivity depending on the skill of the operator and the severity of the disease. Ultrasonography has a higher sensitivity for classical acute pancreatitis in both dogs and cats because associated edema and peripancreatic fat necrosis result in visible interfaces. The sensitivity is much lower for chronic pancreatitis in both cats and dogs (Fig. 40-6).

# Fluid Analysis

Some dogs and cats with pancreatitis have abdominal effusion. Fluid analysis usually reveals serosanguineous sterile exudates, although transudates and chylous effusions have also been reported in cats. Amylase and lipase activities in the fluid may be higher than in the serum, and elevated lipase in the effusion can be diagnostically helpful (Guija de Arespacochaga et al., 2006). Pleural effusions also occur in a small number of dogs with acute pancreatitis as a result of generalized vasculitis.

The search continues for the ideal diagnostic test for pancreatitis. Trypsin-activation peptide (TAP) is well conserved between species, so human ELISAs can be used for dogs and

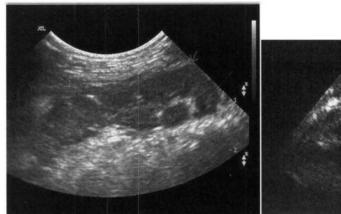

#### FIG 40-5

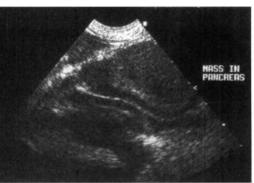

Lateral abdominal radiograph from a 7-year-old Jack Russell Terrier with acute pancreatitis. There are minimal changes apparent apart from a mild loss of abdominal contrast, in spite of the severity of the disease. This does, however, help to rule out acute obstruction because the intestinal loops are not dilated and gas filled. (Courtesy the Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge.)

cats. However, elevations in either plasma or urine TAP are no more sensitive or specific than currently available blood tests. In dogs the best prognostic indicator is the modified organ score, as shown in Tables 40-6 and 40-7. This system has been extrapolated from humans, but its use as a prognostic and treatment indicator in cats has not been critically evaluated. Of the individual diagnostic tests, the following were found to be negative prognostic indicators in dogs: high urinary TAP: creatinine ratio, marked increases in serum lipase activity, marked increases in serum creatinine and phosphate concentrations, and low urine specific gravity. In cats, the following negative prognostic indicators were found: low ionized calcium and leukopenia. Urinary or plasma TAP do not appear to be prognostically useful in cats, and neither does the degree of elevation of TLI in either species. The prognostic significance of degree of elevation of cPLI activity is currently unknown.

# Histopathology

Definitive diagnosis of acute pancreatitis can be achieved only via histopathology of a pancreatic biopsy, but this is invasive and not indicated in most cases. However, if the animal has a laparotomy during its investigation, the clinician should always remember to visually inspect the pancreas and also, preferably, to obtain a small biopsy. The pancreas usually appears grossly inflamed and may have a masslike appearance. The latter is usually due to fat necrosis and/or fibrosis and not neoplasia; therefore no animal should be euthanized on the basis of a tumorlike appearance in the pancreas without supportive cytology or pathology because most large masses in the pancreas are not tumors. As in the small intestine, it is possible for the pancreas to appear grossly normal despite having clinically relevant disease, particularly in cats and in dogs and cats with low-grade chronic

В

# FIG 40-6

**A,** Typical ultrasonographic appearance of acute pancreatitis in a Miniature Schnauzer with a diffusely hypoechoic pancreas *(white arrows)* with surrounding hyperechoic mesentery. **B,** Typical ultrasonographic appearance of chronic pancreatitis in an English Cocker Spaniel. There is a masslike effect displacing the duodenum. Many dogs and cats with chronic pancreatitis have an unremarkable abdominal ultrasound. (Courtesy the Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge.)

disease. Pancreatic biopsy is safe and does not carry a high risk of postoperative pancreatitis, provided that the pancreas is handled gently and the blood supply is not disrupted. It is best to take a small biopsy from the tip of a lobe and not to ligate any vessels, particularly on the right limb, which shares a blood supply with the proximal duodenum.

However, in most cases a biopsy will not be performed and diagnosis is based on a combination of clinical suspicion, specific enzyme tests, and diagnostic imaging. No one non-invasive test is 100% sensitive and specific for pancreatitis in dogs and cats; in a few cases of even severe disease, all the tests may be negative.

# **Treatment and Prognosis**

The treatment and prognosis of dogs and cats with acute pancreatitis depends on the severity of the condition at presentation. Severe acute pancreatitis is a very serious disease, has a very high mortality, and requires intensive management, whereas more moderate disease can be managed with intravenous fluids and analgesia, and patients with mild disease can sometimes be managed on an outpatient basis.

The easiest and most practical way to scale treatment and prognosis in dogs is to use the organ-scoring system modified from human medicine by Ruaux and Atwell (1998) and Ruaux (2000; see Tables 40-6 and 40-7). Cats, even those with severe disease, are more difficult to assess because of their mild clinical signs and because the utility of the organ-scoring system has not yet been assessed in this species. It therefore seems prudent to assume that all cats have severe disease unless proved otherwise and treat them intensively, with the intent of preventing hepatic lipidosis and other fatal complications.

The inciting cause of the pancreatitis should be treated or removed in the few cases where it is known (e.g., hypercalcemia or drug-induced), and every effort should be made during treatment to avoid further potential triggers, as outlined in Table 40-3. Most cases of pancreatitis are, however, idiopathic, and treatment is largely symptomatic. The one

TABLE 40-6

Modified Organ Scoring System for Treatment and Prognostic Decisions in Acute Pancreatitis

SEVERITY AND DISEASE SCORE*		PROGNOSIS	EXPECTED MORTALITY %
Mild	0	Excellent	0
Moderate	1	Good to fair	11
	2	Fair to poor	20
Severe	3	Poor	66
	4	Grave	100

<sup>\*</sup> The severity scoring system is based on the number of organ systems apart from the pancreas showing evidence of failure or compromise at initial presentation; see Table 40-7 for details on scoring. This scoring system was developed for acute pancreatitis in dogs. It is unclear whether this system can be applied to cats or to acute-on-chronic pancreatitis in dogs.

From Ruaux CG et al: A severity score for spontaneous canine acute pancreatitis, Austr Vet J 76:804, 1998; and Ruaux CG: Pathophysiology of organ failure in severe acute pancreatitis in dogs, Compend Cont Edu Small Anim Vet 22:531, 2000.

**TABLE 40-7** 

Criteria to Assess Organ System Compromise for Severity Scoring System in Canine Acute Pancreatitis

ORGAN SYSTEM	CRITERIA FOR COMPROMISE	LAB REFERENCE RANGE
Hepatic	One or more of alkaline phosphatase, aspartate aminotransferase, or alanine aminotransferase >3× upper reference range	
Renal	Blood urea >84 mg/dl	Blood urea 15-57 mg/dl
	Creatinine >3.0 mg/dl	Creatinine 0.6-1.8 mg/dl
Leukocytic	>10% band neutrophils or total white cell count >24 × 103/µl	Band neutrophils 0.0-0.2 × 103/µl Total white cell count 4.5-17 × 103/µl
Endocrine pancreas*	Blood glucose >234 mg/dl and/or β-OH butyrate >1 mmol/l	Blood glucose 59-123 mg/dl β-OH butyrate 0.0-0.6 mmol/l
Acid/base buffering*	Bicarbonate <13 or >26 mmol/l and/or anion gap <15 or >38 mmol/l	Bicarbonate 15-24 mmol/l Anion gap 17-35 mmol/l

<sup>\*</sup> If increased glucose, butyrate, and acidosis co-exist, count as one system.

From Ruaux CG et al: A severity score for spontaneous canine acute pancreatitis, Austr Vet J 76:804, 1998.

exception is chronic pancreatitis in English Cocker Spaniels, which may be an immune-mediated disease in which steroids and other immunosuppressive drugs may be indicated as a specific treatment (see the section on chronic pancreatitis for more details). Occasionally, Cocker Spaniels with chronic pancreatitis present with acute clinical signs, and judicious corticosteroid therapy might be considered in these individuals. However, there is no evidence that corticosteroid therapy helps in other breeds of dogs, including terriers, and in these the use of such drugs might actually worsen prognosis by increasing the risk of gastric ulceration and reducing the activity of the reticuloendothelial system in the removal of circulating \alpha\_2-macroglobulin-protease complexes. In some instances, a dog or cat may need corticosteroid therapy for a concurrent condition, such as immune-mediated hemolytic anemia or inflammatory bowel disease, in which case the benefits of corticosteroids may outweigh their potential deleterious effects.

Severe, necrotizing pancreatitis (scores 3 and 4; Tables 40-6 and 40-7) carries a poor to very poor prognosis in both cats and dogs. These patients have severe fluid and electrolyte abnormalities associated with systemic inflammatory disease, renal compromise, and a high risk of DIC. Intensive management is required, including plasma transfusions in many cases and enteral tube feeding or total parenteral nutrition in some (see next section). These patients will likely benefit from referral to a specialist. If referral is not an option, intensive therapy can be attempted in the practice, but the owner must be warned of the very poor prognosis and expense of treatment.

At the other end of the spectrum, patients with very mild pancreatitis (score 0) may simply need hospitalization for 12 to 24 hours of intravenous fluid therapy if they are vomiting and dehydrated; if they are alert and well-hydrated, they may be managed at home with 24 to 48 hours of pancreatic rest (fluids only by mouth) and analgesia followed by long-term feeding of an appropriate diet.

It is important to give consideration to the following aspects of treatment in all patients: intravenous fluid and electrolyte replacement; analgesia; nutrition; and other supportive therapy, as indicated, such as antiemetics and antibiotics.

# Intravenous Fluids and Electrolytes

Intravenous fluid therapy is very important in all but the mildest cases of pancreatitis to reverse dehydration, address electrolyte imbalances associated with vomiting and fluid pooling in the hypomotile gastrointestinal tract, and maintain adequate pancreatic circulation. It is vital to prevent pancreatic ischemia associated with reduced perfusion because it contributes to necrosis. Replacement fluids (e.g., lactated Ringer's or Plasmalyte) are usually used at rates and volumes that depend on the degree of dehydration and shock—twice maintenance (100 to 120 ml/kg/day) rates are adequate for mild to moderately affected animals (grades 0 and 1), but more severely affected animals may need initial shock rates (90 ml/kg/hour for 30 to 60 minutes) followed

by synthetic colloids. It is important to measure urine output concurrently. Rapid crystalloid infusion in severely affected animals that have a pathological increase in vascular permeability carries an increased risk of pulmonary edema, so patients should be closely monitored; central venous pressure ideally should be measured in the most severely affected dogs.

Serum electrolyte concentrations should be carefully monitored. Potential electrolyte abnormalities are outlined in Table 40-4, but the most clinically important abnormality in most cases is hypokalemia caused by vomiting and reduced food intake. Hypokalemia can significantly impair recovery and contribute to mortality because it causes not only skeletal muscle weakness but also gastrointestinal atony, which will contribute to the clinical signs of the disease and delay successful feeding. Aggressive fluid therapy further increases renal potassium loss, particularly in cats, so it is important to measure serum potassium concentrations frequently (at least daily while the patient is vomiting) and add supplemental potassium chloride to the fluids as necessary. A scaled approach is best, based on the degree of hypokalemia. Lactated Ringer's or Plasmalyte contains only 4 mEq/l potassium, and most cases require supplementing at least to replacement rates (20 mEq/l). Even if serum potassium concentration cannot be measured, a vomiting anorexic dog with no evidence of renal failure should receive replacement rates of potassium in the fluids. More severely hypokalemic dogs should be supplemented more, as long as serum concentrations can be regularly measured and infusion rates carefully controlled. A dog or cat with a serum potassium concentration of 2.0 mEq/l or less should receive between 40 and 60 mEq/l in the fluids at a controlled infusion rate. As a general rule, the infusion rate of potassium should still not be increased above 0.5 mEq/kg/hour.

A plasma transfusion is indicated in dogs and cats with severe pancreatitis (organ score 2 to 4) to replace  $\alpha_1$ -antitrypsin and  $\alpha_2$ -macroglobulin. It also supplies clotting factors and may be combined with heparin therapy in animals at high risk of DIC, although the efficacy of heparin therapy in DIC in humans and animals has recently been questioned and there are no controlled trials that either support or refute its use in pancreatitis in dogs and cats at present.

# **Analgesia**

Pancreatitis is usually a very painful condition in humans and animals. Hospitalized patients should therefore be monitored carefully for pain, and analgesia should be administered as necessary. In practice, analgesia is indicated in almost all patients with pancreatitis and should be given routinely to cats with pancreatitis because pain is difficult to assess in this species. Morphine agonists or partial agonists are often used, particularly buprenorphine. Morphine, meperidine, and fentanyl (intravenous or patches) can also be used (Table 40-8). Concerns that the effects of opiates on the sphincter of Oddi might exacerbate disease have often been cited with regard to dogs as well as humans, but more recent studies

TABLE 40-8

	INDICATIONS AND	DOSE AND	DOSE AND	
ANALGESIC	CAUTIONS	ROUTE: DOGS	ROUTE: CATS	NOTES
Buprenorphine	Most generally useful analgesic in hospitalized case Cats (but not dogs) may be dosed orally at home	IV, SC, IM: 0.01- 0.02 mg/kg	IV, SC, IM as dogs Orally in cats (Robertson et al., 2003)	Concerns about effects on Sphincter of Oddi largely unfounded
Butorphanol	Authors have very limited experience of its use—other opiates preferred in acute pancreatitis because of butorphanol's cardiovascular effects (see notes)	0.05-0.6 mg/kg IM, SC, or IV q6-8h; 0.1-0.2 mg/kg/h as a CRI Oral: 0.5-1 mg/kg q6-12h	As dogs	At analgesic doses in humans it increases pulmonary artery pressure and cardiac work, unlike the other analgesics in the table, so other opiates preferred
Meperidine (Demerol)	Meperidine by injection only, hence hospitalized animals NOT for IV administration	5 mg/kg SC, IM q2h	3-5 mg/kg SC, IM q2h	Painful on injection Is derived from atropine and therefore, in contrast to the other opioids, is a spasmolytic agent on smooth muscle—might be useful for the gut
Methadone	Little nausea or vomiting so more useful than morphine	0.2-0.4 mg/kg SC or IM q4-6h or as required	0.2 mg/kg SC or IM q4-6h or as required	Can produce dysphoria
Hydromorphone	•	0.05 mg/kg IV q4h; 0.1-0.4 mg/kg IM	0.1 mg/kg IM q7h	Can produce dysphoria
Fentanyl patches	Very useful, care with home discharge	2-4 μg/kg/h patch	25 μg/h patch with half exposed	24-hour onset and 72-hour duration in dogs; 7-hour onset and 72-hour duration in cats
Tramado <b>l</b>	Authors have no personal experience of using this in acute pancreatitis but may be a useful drug for home use orally for mild to moderate pain.	Oral: 2-5 mg /kg q8-12h	Oral: 2-4 mg/ kg q 8-12 h	Tramadol also decreases cardiac contractility; shoul not be used in acute phas when myocardial depressal factor may be released. No published studies on pharmacokinetics in small animals so doses empirical Dysphoria more likely in car
Ketamine infusion	Severe refractory pain in hospitalized patient	2 μg/kg/min	As dogs	Useful as adjunct, probably not suitable as sole analgesic; can produce dysphoria at higher infusion rates
Lidocaine infusion	Excellent analgesic for hospitalized patients	Bolus of 1 mg/kg IV followed by 20 µg/kg/min infusion	0.1 mg/kg/h	Use with caution in cats because of lidocaine toxicity
Acetaminophen (Paracetamol)	Mainstay nonsteroidal in human pancreatitis; often neglected in dogs, but useful because it does not have the same deleterious effects on the gastrointestinal tract and kidneys	10 mg/kg orally q12h	DO NOT USE as is toxic	Should not be used if significant concurrent liver disease

**TABLE 40-8** 

Details of Analgesics Used on Acute Pancreatitis—cont'd

ANALGESIC	INDICATIONS AND CAUTION	DOSE AND S ROUTE: DOGS	DOSE AND ROUTE: CATS	NOTES
Carprofen and other nonsteroidal antiinflammatory drugs	with great care because of potential gut and renal	Carprofen: 4 mg/kg SC, IV, or orally q24h; maintain on 2 mg/kg q12h	Carprofen: 2 mg/kg SC, IV, or orally; maintain on 2 mg/kg	Underestimated efficacy COX 1:2 inhibition ratio of 65

(With thanks to Dr. Jackie Brearley, Senior Lecturer in Veterinary Anaesthesia, the Queen's Veterinary School Hospital, University of Cambridge, UK.)

have suggested minimal clinically relevant effects, except when high and repeated doses of morphine are used; these drugs are regularly used now in humans with pancreatitis with no obvious problems. Fentanyl patches take time to achieve effect (on average, 24 hours in dogs and 7 hours in cats), so concurrent use of an opiate for the first few hours after application is recommended. Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided if possible because of the increased risk of gastroduodenal ulceration in patients with pancreatitis and also the potential of some NSAIDs to precipitate renal failure in animals with hypotension and/or shock. In people acute pancreatitis has been associated with the use of NSAIDs. Cyclo-oxygenase-2 inhibitors have a lower risk ratio than the conventional NSAIDs in this respect. Alternative analgesics that could be considered in severe cases include a low-dose intravenous ketamine infusion, which has the advantage of minimal effect on gastrointestinal motility (Bares et al., 1995) or intravenous lidocaine. Details of analgesia are given in

Providing analgesia that can be dispensed for the client to take home in patients with milder or resolving disease can be a challenge. The pain should not be underestimated in these patients. However, it is difficult to find effective and safe analgesia that can be dispensed for use at home. Administration of opioids during visits to the clinic is wise, and one of the less ulcerogenic NSAIDs could be used cautiously at home. Cats can be effectively dosed with buprenorphine orally (Robertson et al., 2003), allowing simple home medication, but the oral route is not effective in dogs. Anecdotally, Tramadol has been found to be helpful in dogs. Feeding a low-fat diet helps reduce postprandial pain in humans and anecdotally helps some dogs significantly. However, administering pancreatic enzymes in the food does not seem to reduce pain in dogs, and there is little evidence in support of their use for pain relief in either dogs or cats.

# **Nutrition**

It is very important to consider appropriate nutritional management of the patient with pancreatitis. Complete pancreatic rest by starvation, avoiding anything by mouth (including water or barium), has traditionally been advised for patients with acute pancreatitis. Initially, it was believed that early enteral nutrition was contraindicated because it was likely to result in cholecystokinin and secretin release, with consequent release of pancreatic enzymes and worsening of pancreatitis and associated pain. Total parenteral nutrition (TPN) seemed a more logical route early in the disease process, with jejunal tube feeding later in the disease aiming to bypass the areas of pancreatic enzyme stimulation. However, recent studies have suggested that early enteral nutrition is preferable to TPN, and current best practice in human medicine is outlined in Box 40-1 along with relevance to veterinary patients. It is no longer appropriate or acceptable to starve the patient for days and days while awaiting resolution of disease. Increasing evidence is accumulating in human medicine of the importance of early enteral nutrition in patients with pancreatitis, and emerging work in humans suggests that immunomodulating nutrients may also be of benefit. There are no studies evaluating the efficacy of early or late enteral or parental nutrition in naturally occurring pancreatitis in dogs or cats. Therefore the advice currently given is based on anecdotal evidence, extrapolation from humans, and on experimental studies in dogs only.

However, early feeding of an appropriate diet is now indicated in dogs. In addition, starvation is contraindicated in cats because of the high risk of hepatic lipidosis. The current advice is therefore to institute some form of enteral feeding, whenever possible, within 48 hours in both dogs and cats. The more severe the disease, the more important it is to feed early. In severe cases this is best achieved with jejunostomy tube feeding by continuous infusion of an elemental diet,

IV, Intravenous; SC, subcutaneous; IM, intramuscular.

BOX 40-1

# Best Practice for Feeding Patients with Acute Pancreatitis

Recent studies and metaanalyses of studies of nutrition in human acute pancreatitis have led to changes in advice for best-practice feeding in these cases (Meier and Beglinger, 2006). Note that early enteral nutrition is **particularly** indicated in severe disease, which is perhaps unexpected and counter to our current practice in dogs.

- A negative nitrogen balance is common in acute pancreatitis and is associated with a tenfold increase in mortality, although there have been no studies looking at association of disease severity with nitrogen balance. This is also likely to be true in small animals but has not been specifically investigated.
- IV feeding of glucose, protein, or lipids does not stimulate pancreatic secretions. However, whether feeding is IV or enteral, blood glucose should be kept normal because hypoglycemia or hyperglycemia is associated with a negative outcome. Insulin is used if the patient becomes hyperglycemic on feeding, but this should be done only carefully in an intensive care situation with regular (hourly) monitoring of blood glucose.
- Intrajejunal infusion of elemental diets in humans and experimental canine models of pancreatitis does not stimulate pancreatic enzyme release significantly.
- Early oral feeding after acute pancreatitis in humans is associated with increased pain, whereas jejunal feeding is not. This has not been assessed in small animals.
- Important: early intrajejunal feeding is preferred over total parenteral nutrition in patients with acute pancreatitis, particularly severe disease.
   Results of metaanalysis in humans show that intrajejunal feeding after 48 hours significantly reduced incidences of infections, reduced surgical interventions, and reduced length of hospital stay and cost over total parenteral nutrition. These findings have also been replicated in dogs with

- experimental acute pancreatitis but not yet in clinical pancreatitis in dogs, although the experiences from early enteral feeding in other gastrointestinal diseases in this species, such as parvovirus enteritis (Mohr et al., 2003), suggest that the recommendations may be similar. Most recently, it has been suggested that feeding may even be given safely intragastrically in humans with acute pancreatitis, although more studies are needed to confirm this.
- Type of diet used: In humans, elemental diets have been used in most cases and usually by continuous infusion. No studies have really assessed whether less elemental diets would also work. Recent studies looking at immune-modulating micronutrients in the diets, such as glutamine, fiber, arginine, omega-3 fatty acids, and probiotic bacteria, have been encouraging (Pearce et al., 2006), but more studies are needed before definite conclusions can be drawn. No similar studies have been undertaken in dogs and cats.
- In mild acute pancreatitis in humans current best practice is to withhold food in many cases for a little longer. Fluids, electrolytes, and analgesics are delivered for 2 to 5 days, and then a diet rich in carbohydrate and moderate in fat and protein is initiated with discharge on a normal diet within 4 to 7 days. Again, there are no specific recommendations for mild acute disease in dogs and cats.
- In cats: Current anecdotal recommendations are to feed immediately in mild, moderate, and severe pancreatitis, preferably via a jejunostomy tube, although again it has been suggested that gastrostromy tubes with multiple low-volume feeds should also be safe. There is just one case report of using an endoscopically placed J-tube in a cat with acute pancreatitis (Jennings et al., 2001). The emphasis on early feeding in cats comes from the risk of hepatic lipidosis.

although frequent small-volume feeds of a low-fat food via a gastrostomy tube is also well tolerated in most dogs and cats with moderate pancreatitis. A good initial choice is baby rice mixed with water followed by a low-fat proprietary veterinary diet (such as Eukanuba Intestinal Formula; Hill's i/d; Royal-Canin-Waltham Digestive low fat or Purina Enformula) (Fig. 40-7). Concurrent antiemetics are also essential to allow effective feeding in many cases (see next section). In patients in which enteral nutrition is not possible or when only a small percentage of the daily caloric requirements can be given enterally, some form of supplemental parenteral nutrition should be considered. This is most practically administered as peripheral parenteral nutrition (see Chandler et al., 2000).

# **Antiemetics**

Antiemetics are often necessary to manage acute vomiting in dogs and cats with pancreatitis. Metoclopramide has been used successfully in dogs with pancreatitis (0.5 to 1 mg/kg,

administered intramuscularly, subcutaneously, or orally three times a day, or 1 to 2 mg/kg, administered intravenously over 24 hours as a slow infusion), but its effect on stimulating gastric motility may increase pain and pancreatic enzyme release in some animals. A phenothiazine antiemetic such as chlorpromazine may be more effective in some patients, but phenothiazines have sedative and hypotensive effects, which may be particularly marked if they are used together with opioid analgesia, so care should be taken in these cases. 5-HT3 receptor antagonists such as ondansetron are useful in other forms of vomiting in dogs (such as chemotherapy-induced emesis) but are best avoided in pancreatitis because they have occasionally been reported to trigger pancreatitis in humans. The newly available NK<sub>1</sub> receptor antagonist maropitant, licensed for use in dogs, has both central and peripheral antiemetic effects and is showing promise as an antiemetic in dogs with pancreatitis, although it is not licensed for use in cats. (Maropitant is available as Cerenia (Pfizer) in either an injectable solution (10 mg/ml)

Baby rice is a good first choice for feeding dogs with acute pancreatitis because it contains no fat and protein. It comes as a finely ground rice powder (A) that can then be mixed with water and, if desired, a gravy substitute such as Bovril to enhance the flavor for feeding (B).

or tablets (16 mg, 24 mg, and 60 mg). The dose of injection is 1 mg/kg (i.e., 1 ml per 10 kg body weight once a day for up to 5 days). The dose of the tablets is 2 mg/kg once a day for up to 5 days.

# Gastroprotectants

Patients with acute pancreatitis have an increased risk of gastroduodenal ulceration caused by local peritonitis; they should be monitored carefully for evidence of this (melena, hematemesis) and treated as necessary with sucralfate and acid secretory inhibitors (H<sub>2</sub> blockers such as cimetidine, famotidine, ranitidine, or nizatidine or the proton pump inhibitor omeprazole). Cimetidine should be avoided in animals with concurrent liver disease because of its effect on the cytochrome P450 system. Ranitidine can be used instead in these animals, but its additional gastric prokinetic effect can cause vomiting in some individuals; it should be discontinued if this occurs. Because famotidine does not have these prokinetic effects, it may be preferable.

## **Antibiotics**

Infectious complications are reportedly rare in dogs and cats with pancreatitis, but when they occur, they can be serious; antibiotic therapy has been shown to improve survival in such cases in humans. It is therefore advisable to use broadspectrum antibiotics in dogs and cats with acute pancreatitis because it is not always possible to assess the occurrence or risk of septic complications. Fluroquinolones or potentiated sulphonamides have been used in humans because they penetrate the pancreas well and are effective against most human bacterial isolates from this region. However, because potentiated sulphonamides are potentially hepatotoxic, they are best avoided if there is concurrent hepatic involvement; fluroquinolones are effective against only aerobes, so combination with another antibiotic with action against anaerobes, such as metronidazole or amoxicillin, may be necessary. Metronidazole has the added benefit of being beneficial if there is concurrent inflammatory bowel disease or small intestinal bacterial overgrowth secondary to intestinal ileus.

# Treatment of Biliary Tract Obstruction Associated with Pancreatitis

Most cases of extrahepatic biliary obstruction secondary to acute-on-chronic pancreatitis resolve with conservative management, and surgical or needle decompression of the gallbladder and stenting of the bile duct are usually unnecessary in dogs and cats. In humans it has now been demonstrated that there is no advantage to surgical intervention in most patients and no difference in the severity and chronicity of secondary liver disease between those treated medically and those treated surgically, provided the jaundice resolves within a month (Addallah et al 2007). No such study has been done in small animals, so treatment advice has to be empirical: If the feces remain colored (not white or acholic, which implies complete biliary obstruction) and the jaundice gradually resolves over a week to 10 days, then surgical intervention is not indicated and conservative management with antioxidants and ursodeoxycholic acid are advised (see Chapters 37 and 38).

# **CHRONIC PANCREATITIS**

# **Etiology and Pathogenesis**

Chronic pancreatitis is defined as "a continuing inflammatory disease characterized by the destruction of pancreatic parenchyma leading to progressive or permanent impairment of exocrine or endocrine function or both." The gold standard for diagnosis is histology (see Fig. 40-2), but this is rarely indicated or performed in dogs or cats. Noninvasive diagnosis is difficult with the currently available diagnostic imaging, and blood tests have a lower sensitivity than for acute disease.

Chronic pancreatitis has been considered a rare and not particularly important disease in dogs, whereas it is recognized as the most common form of pancreatitis in cats. However, the early literature published on canine pancreatic disease in the 1960s and 1970s recognized it as a common disease of clinical significance. It was noted that a high proportion of cases of EPI in dogs were caused by chronic

pancreatitis and also that it might be responsible for up to 30% or more of cases of diabetes mellitus (DM). More recent pathological and clinical studies in both dogs (Newman et al., 2004; Watson et al., 2007) and cats (DeCock et al., 2007) have reconfirmed it as a common and clinically relevant disease in both dogs and cats. It is likely to cause intermittent and/or ongoing recurrent gastrointestinal signs and epigastric pain in a high number of dogs and cats, but it is frequently underrecognized because of the difficulty of obtaining a noninvasive diagnosis. In dogs the postmortem prevalence of chronic pancreatitis is up to 34%, particularly in susceptible breeds, and even in studies of fatal acute pancreatitis, acute-on-chronic disease accounts for 40% of cases. In cats an even higher postmortem prevalence of chronic pancreatitis of 60% has been reported. It must be noted that postmortem studies tend to overestimate the prevalence of chronic diseases, which leave permanent architectural changes in the organ, whereas the prevalence of acute, totally reversible diseases will be underestimated, unless the animal dies during the episode. Nevertheless, it is clear that there are many more cases of chronic pancreatitis in veterinary practice than currently recognized and that a number of these are clinically relevant.

# **Idiopathic Chronic Pancreatitis**

As in acute pancreatitis, the cause of chronic pancreatitis in dogs is usually unknown (see Table 40-3). Any age or breed of dog can be affected, but the most typical signalment is a middle-aged to old dog, particularly a Cavalier King Charles Spaniel, Cocker Spaniel, Collie, or Boxer in the U.K. (Watson et al., 2007; Fig. 40-8). The breed prevalence in the U.S. has not been investigated, but an independent large study of EPI in the U.K. found an increased prevalence in older Cavalier King Charles Spaniels, supporting this breed association. Other parts of the world have also reported a high incidence in arctic-type breeds such as Huskies. There is likely to be some overlap with acute disease, although

FIG 40-8
An 8-year-old neutered male English Cocker Spaniel with chronic pancreatitis.

some cases will have a separate etiology. Some cases may represent chronic relapsing cases of acute disease, but many cases are truly chronic from the outset, with an initial mononuclear infiltrate. Genetic causes are likely to be important in dogs, which explains the increased risk in certain breeds.

No particular breed prevalence has been reported for cats with chronic pancreatitis, and domestic shorthairs are most commonly affected.

# **Autoimmune Chronic Pancreatitis**

The particular form of chronic pancreatitis recognized in English Cocker Spaniels in the U.K. is thought to be an autoimmune disorder (Watson et al., 2006b; see Fig. 40-8). As in human autoimmune pancreatitis, it typically affects middle-aged to older dogs, with a higher prevalence in males, and at least 50% of affected dogs subsequently develop DM, EPI, or both. Dogs also often have other concurrent autoimmune disease, particularly keratoconjunctivitis sicca. There is often a mass-like lesion on ultrasound (see Fig. 40-6, B), and biopsies show a typical perilobular diffuse fibrotic and lymphocytic disease centered on perilobular ducts and vessels, with loss of large ducts and hyperplasia of smaller ducts. Immunohistochemistry shows a preponderance of duct and vein-centered CD3+ lymphocytes (i.e., T-cells). The human disease is believed to be a duct-centered immune reaction and responds to steroid therapy, including a reduction in insulin requirement in some diabetics. This is clearly differentiated from the proposed autoimmunity in young German Shepherd Dogs with pancreatic acinar atrophy, which is acinar-centered and does not result in DM (discussed in more detail later). There are not yet any controlled trials evaluating the use of immunosuppressive drugs in English Cocker Spaniels with chronic pancreatitis, but there is now enough circumstantial evidence to justify their use in this particular breed. However, the clinician should note that this is very breed specific; terriers in the U.K., for example, have a very different histopathological and clinical picture of disease that does not appear to be autoimmune, and the use of steroids in terriers with chronic pancreatitis is not recommended.

# **Clinical Features**

Dogs with chronic pancreatitis, regardless of the cause, most commonly present with mild intermittent gastrointestinal signs. Typically, they have bouts of anorexia, occasional vomiting, mild hematochezia, and obvious postprandial pain, which often goes on for months to years before a veterinarian is consulted. The trigger for finally seeking veterinary attention is often an acute-on-chronic bout or the development of DM or EPI. The main differential diagnoses in the low-grade cases are inflammatory bowel disease and primary gastrointestinal motility disorders. Dogs may become more playful and less picky with their food when they are switched to a low-fat diet, which suggests that they previously had postprandial pain. Chronic epigastric pain is a hallmark of the human disease and is sometimes severe enough to lead

to opiate addiction or surgery, so it should not be overlooked or underestimated in small animal patients. In more severe, acute-on-chronic cases, the dogs are clinically indistinguishable from those with classical acute pancreatitis (see preceding section), with severe vomiting, dehydration, shock, and potential multiorgan failure. The first clinically severe bout tends to come at the end of a long (often years) subclinical phase of quietly progressive and extensive pancreatic destruction in dogs. It is very important for clinicians to be aware of this because these dogs are at much higher risk for developing exocrine and/or endocrine dysfunction than those with truly acute pancreatitis; in addition, they usually already have protein-calorie malnutrition at presentation, which makes their management even more challenging. It is also relatively common for dogs with chronic pancreatitis to first present with signs of DM and a concurrent acute-on-chronic bout of pancreatitis resulting in a ketoacidotic crisis. In some dogs there are no obvious clinical signs until the development of EPI, DM, or both. The development of EPI in a middle-aged to older dog of a breed not typical for pancreatic acinar atrophy has to increase the index of suspicion for underlying chronic pancreatitis. The development of EPI or DM in a dog or cat with chronic pancreatitis requires the loss of approximately 90% of exocrine or endocrine tissue function, respectively, which implies considerable tissue destruction and end-stage disease.

In cats the clinical signs of chronic pancreatitis are usually very mild and nonspecific. This is not surprising considering that cats display mild clinical signs, even in association with acute necrotizing pancreatitis. One study showed that the clinical signs of histologically confirmed chronic nonsuppurative pancreatitis in cats were indistinguishable from those of acute necrotizing pancreatitis (Ferreri et al., 2003). However, chronic pancreatitis in this species is significantly more often associated with concurrent disease than acute pancreatitis, particularly inflammatory bowel disease, cholangiohepatitis, hepatic lipidosis, and/or renal disease. The clinical signs of these concurrent diseases may predominate, further confusing diagnosis. Nevertheless, some cats will eventually develop end-stage disease with resultant EPI and/or DM.

Chronic pancreatitis is the most common cause of extrahepatic biliary obstruction in dogs (see Chapter 38), and dogs and cats with acute-on-chronic pancreatitis frequently develop jaundice.

# **Diagnosis**

# **NonInvasive Diagnosis**

In the absence of a biopsy, which is the gold standard, the clinician must rely on a combination of clinical history, ultrasonography, and clinical pathology. The findings on diagnostic imaging and clinical pathology are similar to those outlined in the section on acute pancreatitis and Tables 40-4 and 40-5. However, changes tend to be less marked in dogs and cats with chronic pancreatitis, and the diagnostic sensitivity of all tests is lower. Ultrasonography has a lower sensitivity in dogs and cats with chronic disease because

there is less edema than in those with acute disease. A variety of ultrasonographic changes may be seen in patients with chronic pancreatitis, including a normal pancreas, a mass lesion, a mixed hyperechoic and hypoechoic appearance to the pancreas, and sometimes an appearance resembling that of classical acute pancreatitis with a hypoechoic pancreas and a bright surrounding mesentery (Watson et al 2006b; see Fig. 40-6). In addition, in patients with chronic disease adhesions to the gut may be apparent, and the anatomy of the pancreatic and duodenal relationship may be changed by these adhesions. Some patients (particularly Cocker Spaniels) have large mass-like lesions associated with fibrosis and inflammation; some cases have tortuous and dilated, irregular ducts; and many cases have completely normal pancreatic ultrasonographic findings in spite of severe disease.

Likewise, clinical pathology can be helpful, but the results may also be normal. Increases in pancreatic enzyme acitivities are most likely to be seen during an acute-on-chronic bout than during a quiescent phase of disease (very similar to the waxing-and-waning increases in liver enzyme activities in patients with ongoing chronic hepatitis). Again, similar to the situation in hepatic cirrhosis, in end-stage chronic pancreatitis there may not be enough pancreatic tissue left to produce increases in enzyme activities, even in acute flare-ups. On the other hand, occasionally serum TLI can temporarily increase into or above the normal range in dogs with EPI as a result of end-stage chronic pancreatitis, confusing the diagnosis of EPI in these dogs. cPLI appears to have the highest sensitivity for the diagnosis of canine chronic pancreatitis, but even this has a lower sensitivity than in acute disease. The diagnostic sensitivity of feline PLI for chronic pancreatitis in cats is unknown.

It is important to measure serum B<sub>12</sub> concentrations in dogs and cats with chronic pancreatitis. The gradual development of EPI, combined often with concurrent ileal disease particularly in cats, predisposes to cobalamin deficiency, as outlined in the section on EPI. If serum B<sub>12</sub> concentration is low, cobalamin should be supplemented parenterally (0.02 mg/kg, administered intramuscularly or subcutaneously every 2 weeks in dogs and cats until serum concentration is normalized).

## Biopsy

The diagnosis of chronic pancreatitis can be very difficult in dogs and cats, and difficulties in diagnosis likely result in under-recognition of the disease. Establishing a definitive diagnosis relies on obtaining a pancreatic biopsy. However, this will not be indicated in most cases until there are effective treatments because a biopsy is a relatively invasive procedure, the results of which do not alter treatment or outcome. However, with the potential for some more specific therapies, routine biopsy may be indicated in the future. In humans the preferred method is needle-biopsy via transendoscopic ultrasonographic guidance. Transendoscopic ultrasonography is very expensive and of limited availability in veterinary medicine, so in dogs and cats surgical or laparo-

scopic biopsies remain the most applicable. Cytology of ultrasound-guided transcutaneous fine needle aspirates of the pancreas may help differentiate neoplasia or dysplasia from inflammation, but veterinary experience in this area is very limited. If the clinician is performing a laparotomy to obtain other biopsies, it makes perfect sense to obtain a pancreatic biopsy at that time as well. Pancreatitis is not a risk, provided the pancreas is handled gently and the blood supply is not disrupted. However, the biopsy should be small and from the tip of a lobe and may therefore miss the area of disease, which is usually patchy, particularly early on, and can also be centered on large ducts. Unfortunately therefore, even biopsy has its limitations.

# **Treatment and Prognosis**

Dogs and cats with chronic, intermittent pancreatitis may have intermittent bouts of mild gastrointestinal signs and anorexia, and the owner's primary concern is often that the pet has missed a meal. These animals can be managed at home, as long as anorexia is not long lasting, and the owner should be reassured that a short period of self-induced starvation is actually beneficial because it provides pancreatic rest.

As in patients with acute pancreatitis, the current preference is for symptomatic treatment. Dogs and cats with acute flare-ups require the same intensive treatment as dogs and cats with classical acute pancreatitis and have the same risk of mortality (see preceding section). The difference from isolated acute pancreatitis is that if the animal recovers from the acute bout, it is likely to remain with considerable exocrine and/or endocrine functional impairment. In the milder cases symptomatic treatment can make a real difference in the animal's quality of life. Changing to a low-fat diet (such as Hill's ID, Royal-Canin-Waltham Digestive low fat, or Eukanuba Intestinal) apparently reduces postprandial pain and acute flare-ups in many cases. Owners often underestimate the effects of fatty treats, which can precipitate recurrences in susceptible individuals. Some animals need analgesia, either intermittently or continuously (see section on acute pancreatitis and Table 40-8). According to anecdotal reports, short courses of metronidazole (10 mg/kg, PO q12h) seem to help some patients after acute boutspresumably because they develop secondary bacterial overgrowth as a result of a "stagnant loop" phenomenon in the adjacent duodenum. Serum B<sub>12</sub> concentration should be measured regularly, and cobalamin should be supplemented parenterally as necessary (0.02 mg/kg, administered intramuscularly 2 to 4 weeks until serum concentration normalizes).

Treatment of extrahepatic biliary tract obstruction associated with acute-on-chronic disease should be as outlined in the acute pancreatitis section.

In patients with end-stage disease, exocrine and/or endocrine deficiency may develop. Dogs and cats with EPI and/or DM are managed with enzymes (discussed in more detail later) and insulin as necessary in the usual way (see Chapter 52), and most do surprisingly well long term.

#### **EXOCRINE PANCREATIC INSUFFICIENCY**

EPI is a functional diagnosis that results from a lack of pancreatic enzymes. As such, unlike pancreatitis, it is diagnosed on the basis of clinical signs and pancreatic function tests and not primarily the results of pancreatic histopathology, although finding a marked reduction in pancreatic acinar mass on histology is supportive of a diagnosis of EPI. The pancreas is the only significant source of lipase, so fat maldigestion with fatty feces (steatorrhea) and weight loss are the predominant signs of EPI.

# **Pathogenesis**

Pancreatic acinar atrophy (PAA) is believed to be the predominant cause of EPI in dogs, but recent work has shown that end-stage chronic pancreatitis is also important in this species (Fig. 40-9; Watson and Herrtage, 2006a; Batchelor et al., 2007a). PAA has not been recognized in cats; end-stage pancreatitis is the most common cause of feline EPI (Fig. 40-10). The development of clinical EPI requires approximately a 90% reduction in lipase production and thus extensive loss of pancreatic acini. It is therefore extremely unlikely to occur after a severe bout of pancreatitis; it tends to result from chronic, ongoing disease. However, the chronic disease may be largely subclinical or only present as occasional clinical acute-on-chronic episodes, so the degree of underlying pancreatic damage may be underestimated.

PAA is particularly recognized in young German Shepherd Dogs (see Fig. 40-9, A), in which an autosomal mode of inheritance has been demonstrated, and has also been described in Rough Collies, suspected in English Setters, and sporadically reported in other breeds. A recent large study of EPI in the U.K. reported that young Chow Chows were overrepresented (Batchelor et al., 2007a). The pathogenesis was unknown, but the juvenile onset suggested PAA or perhaps a congenital defect in this breed.

Histological studies in German Shepherd Dogs suggest that PAA is an autoimmune disease directed against the acini (Wiberg et al., 2000). Therefore the islets are spared, and dogs with PAA are not typically diabetic. However, affected dogs do not respond to immunosuppressive therapy. Most dogs develop the disease in young adulthood, but a proportion of German Shepherd Dogs remain subclinical for a prolonged period of time and present only late in life.

In contrast, many dogs with end-stage chronic pancreatitis also develop DM either before or after EPI as a result of concurrent islet cell destruction (Watson, 2003; Watson et al., 2006a). The situation is similar in cats with end-stage chronic pancreatitis. There is no breed relationship in cats, but dogs with EPI as a result of end-stage chronic pancreatitis tend to be middle-aged to older medium- or small-breed dogs, particularly Cavalier King Charles Spaniels, English Cocker Spaniels, and Collies (see Fig. 40-8). Interestingly, although Boxers in the U.K. were reported to have an increased prevalence of chronic pancreatitis in one study, they have also been reported to be significantly under-

#### FIG 40-9

**A,** Physical appearance of a 2-year-old male German Shepherd Dog with exocrine pancreatic insufficiency (EPI). **B,** An 11-year-old neutered female English Springer Spaniel with EPI caused by end-stage chronic pancreatitis. This dog also had diabetes mellitus (DM) but was still losing weight in spite of good control of the DM. EPI had not initially been suspected, but once it was diagnosed and treated with enzyme supplements, the dog returned to normal weight and coat condition within 6 months (**C**). (A, Courtesy Dr. William E. Hornbuckle, Cornell University, College of Veterinary Medicine. **B,** From Journal of Small Animal Practice vol. 44, 2003.)

**FIG 40-10**A middle-aged Persian cat with end-stage chronic pancreatitis and exocrine pancreatic insufficiency. Note matting of coat with feces and poor body condition.

represented among dogs with EPI, which suggests that their chronic pancreatitis does not progress to end-stage disease. Other underrepresented breeds in a large study of EPI were Golden Retrievers, Labrador Retrievers, Rottweilers and Weimaraners (Batchelor et al., 2007a). Finding compatible clinical signs in these breeds should first trigger a search for other possible causes, such as chronic infections or inflammatory bowel disease.

Other causes of EPI in dogs and cats are pancreatic tumors, hyperacidity of the duodenum inactivating lipase, and isolated enzyme (particularly lipase) deficiency. These are all rare causes. Patients with pancreatic tumors usually present for other reasons, but tumors can result in EPI owing to a combination of compression of pancreatic ducts by the mass, destruction of acinar tissue, and associated pancreatitis.

Up to 70% of dogs with EPI have concurrent small intestinal bacterial overgrowth (SIBO). This will contribute to clinical signs and should be considered when treating an

affected dog. In SIBO bacteria deconjugate bile salts, thus decreasing fat emulsification and therefore fat digestion. Bacteria also break down the undigested fat to hydroxy fatty acids. These and deconjugated bile salts irritate the colonic mucosa and may cause large intestinal diarrhea by stimulating secretion. Dogs with EPI therefore tend to present with signs of both small and large bowel diarrhea.

A high proportion of dogs (particularly those presenting with low body condition scores) also have reduced duodenal enzyme activity, which may be partly due to the SIBO but also to the effects of malnutrition on the gut and possibly to the loss of the trophic influence of pancreatic secretions. Cobalamin deficiency is common in both dogs and cats with EPI and seems to be a negative prognostic indicator in dogs if untreated (Batchelor et al 2007b). Vitamin B<sub>12</sub> is absorbed from the distal ileum using a carrier-mediated process that requires the vitamin to be bound to intrinsic factor (IF). The latter is produced entirely by the pancreas in cats and mainly by the pancreas in dogs, although the canine stomach can also produce a small amount. Therefore most cats with EPI are expected to be B<sub>12</sub>-deficient, whereas most but not all of dogs with EPI have hypocobalaminemia. In one large study of dogs with EPI, 82% of dogs had low serum cobalamin concentration (Batchelor et al 2007b). In cats with end-stage pancreatitis, the hypocobalaminemia is compounded by the high prevalence of concurrent inflammatory bowel disease, which often decreases ileal absorption of vitamin B<sub>12</sub>. Cobalamin deficiency causes villous atrophy and reduced gastrointestinal function, weight loss, and diarrhea in cats; therefore it is important not only to document hypocobalaminemia but also to treat it with parenteral  $B_{12}$  injections (0.02 mg/kg, administered intramuscularly 2 to 4 weeks until serum concentration normalizes).

#### **Clinical Features**

Most dogs and cats with EPI present because of chronic diarrhea and emaciation in tandem with a ravenous appetite (see Fig. 40-9). The diarrhea tends to be fatty (steatorrhea) because of prominent fat maldigestion but is variable from day to day and among individuals. Sometimes diarrhea is not a prominent feature because digestion is interrupted so early in the process that the osmotic effect of molecules is relatively small. Affected dogs and cats also often have chronic seborrheic skin disease resulting from deficiency of essential fatty acids and cachexia, and some patients present to a dermatology clinic for this reason. If EPI is due to chronic pancreatitis, the diagnosis may be complicated by concurrent ongoing pancreatitis that may cause intermittent anorexia and vomiting. Animals with end-stage chronic pancreatitis may also develop DM either before or months to years after the development of EPI.

Concurrent diseases are common in dogs with EPI, either related or unrelated to the pancreatic deficiency. In one study in dogs concurrent gastrointestinal, skeletal, and skin conditions were common (Batchelor et al 2007b). Cats with pancreatitis often have concurrent cholangitis and/or inflammatory bowel disease, and it is often difficult to differentiate

the clinical signs of the three conditions because they are so similar.

# Diagnosis

## **ROUTINE CLINICAL PATHOLOGY**

CBCs and serum biochemistry profiles are often normal in dogs and cats with EPI. In very cachectic animals there may be subtle nonspecific changes consistent with malnutrition, negative nitrogen balance, and breakdown of body muscle such as low albumin and globulin concentrations, mildly increased liver enzyme activities, low cholesterol and triglyceride concentrations, and lymphopenia.

Finding marked hypoproteinemia or more severe changes on the CBC and biochemistry profiles in an animal with EPI should trigger a search for another concurrent disease. Cats and dogs with end-stage pancreatitis may present with more severe secondary clinicopathologic changes, as outlined in the pancreatitis section. A high percentage of these patients with end-stage pancreatitis (up to 50%) also have concurrent DM, so they have clinicopathological changes typical of DM (see Chapter 52).

#### **PANCREATIC ENZYMES**

The diagnosis of EPI in dogs and cats relies on demonstrating reduced pancreatic enzyme output. The most sensitive and specific way of doing this is by measuring reduced circulating enzyme activity. Blood tests that indirectly measure gut enzyme activity, such as the BT-PABA test, are now rarely used because they have been replaced by the specific immunoassays for serum activities of pancreatic enzymes. Readers who would like more information on the BT-PABA test are referred to Batt et al. (1981). The plasma turbidity test, used historically after feeding a high-fat meal, with and without pancreatic enzymes, had a very low sensitivity and specificity for EPI and has been completely superseded by the enzymatic test.

Measurement of reduced TLI in the blood has a high sensitivity and specificity for the diagnosis of EPI in dogs and cats and is currently the single test of choice for the diagnosis of EPI in small animals. It is important to measure it on a fasting sample because the release of pancreatic enzymes associated with feeding can raise the levels in the serum. It is not necessary to stop exogenous pancreatic enzyme supplementation before measuring TLI because exogenous enzymes should not be absorbed from the gut into the circulation; even if they are, the test is an immunoassay that does not cross-react with the tryspin/trypsinogen of other species in the supplement. However, there are some problems in interpreting the results, as listed in Box 40-2.

Unlike in humans, amylase and lipase activities are not consistently low in dogs and cats with EPI because of the high background levels of enzymes from other organs. A low cPLI also has a good sensitivity and specificity for the diagnosis of EPI in dogs (Steiner et al., 2001). However, this test is not superior to TLI. PLI is also likely to be low in cats with EPI.

BOX 40-2

# Interpretation of TLI Results in the Diagnosis of Canine Exocrine Pancreatic Insufficiency

- A low serum TU (<2.5 µg/l in dogs) in a dog with compatible clinical signs, particularly in a high-risk breed, is diagnostic of EPl</li>
  - A repeat blood sample to confirm diagnosis in a few weeks to months is recommended in cats and in older dogs that are not German Shepherd Dogs. Occasionally, a single TLI may be low in a dog with pancreatitis as a result of a temporary reduction in enzyme production.
- A low serum TU (<2.5 µg/l in dogs) with no compatible clinical signs (i.e., no weight loss or diarrhea) is not diagnostic of EPI but should be repeated
  - A dog with persistently low TLI but no steatorrhea or weight loss should be considered to have subclinical EPI and should not be treated but monitored for any evidence of clinical disease. A TLI stimulation test may give more information about the status of the animal but is rarely performed. Subclinical EPI has been reported in a small number of German Shepherd Dogs with PAA (Wiberg et al 1999) but has not yet been reported in cats. It is uncommon.
- A TLI in the gray area (2.5-5.0 μg/l in dogs) is not diagnostic of EPI and should be repeated in a few weeks to months.
  - In a proportion of dogs (45% in one study: Wiberg et al., 1999), the TLI will return to the normal range.

- In another proportion of dogs (about 10%), the TLI will decrease to the level diagnostic of EPI and in some it may remain in the grey area.
- In an older dog that is not a German Shepherd Dog, TLI values may fluctuate as described below and samples should be repeated when there is no clinically acute flare-up
- A normal TLI in a German Shepherd Dog rules out EPI resulting from PAA, and a search should be made for another cause of the presenting clinical signs.
- A single normal or high TLI in an older nonGerman Shepherd Dog with suspicious clinical signs does not rule out EPI. TLI can transiently and intermittently increase into or above the normal range in dogs with EPI secondary to chronic end-stage pancreatitis if it is measured during a bout of inflammation. This is understandable because EPI reduces TLI but pancreatitis elevates it, so the two conditions occurring concurrently interfere with interpretation of the test. This is likely to be true in cats as well, although it has not been well documented in that species. Therefore in any animal with suspected EPI secondary to chronic pancreatitis, TLI measurements should be repeated, preferably when the animal is showing no clinical signs of pancreatitis. Alternatively, a test for enzyme activity in the gut such as a fecal elastase test could be used in these animals.

Note: A TLI stimulation test could be used in animals with subclinical EPI (low TLI but no clinical signs) or animals with a TLI persistently in the grey area. Pancreatic enzyme output is stimulated either with intravenous cholecystokinin and secretin or with a test meal, and TLI concentrations are measured before and after stimulation (Wiberg et al., 1999). Animals with true clinical EPI show no stimulation, whereas animals with subclinical EPI still have enough enzyme activity to increase their TLI after stimulation. The value of a stimulation test in clinical cases is limited because the decision to treat is based on the clinical signs. It is of more value in monitoring progression of disease for clinical research.

EPI, Exocrine pancreatic insufficiency; PAA, pancreatic acinar atrophy.

Fecal tests for EPI are rarely used because of low sensitivity and specificity compared with serum tests. Measuring fecal trypsin activity has a very low sensitivity and specificity for EPI, as do assessment of fecal proteolytic activity or microscopic examination of feces for undigested fat, starch, and muscle fibers. All these tests have been superseded by measurement of serum TLI and cPLI. Measurement of fecal elastase may have some utility in dogs with EPI as a result of chronic pancreatitis or duct blockage, in which TLI results may be misleading. Elastase appears to have higher sensitivity and specificity than the other fecal tests for the diagnosis of EPI in dogs. Elastase is a pancreatic enzyme, and a speciesspecific ELISA for canine elastase has been developed and is available for commercial use in dogs (Spillman et al., 2000 and 2001). As with canine TLI, because there is no crossreaction with elastase from other species, dogs can remain on enzyme supplementation while the test is performed. There is marked variation in elastase levels in normal canine feces compared with humans. The sensitivity and specificity of the test are improved by taking three separate fecal samples

on three days or using a cut-off value for diagnosis of EPI, which is below this variation in most dogs.

# **OTHER DIAGNOSTIC TESTS**

It is also advisable to measure serum cobalamin concentration in animals with EPI because cobalamin concentration is often reduced because of a deficiency of pancreatic intrinsic factor, as previously explained. If serum  $B_{12}$  concentration is low, it should be supplemented parenterally. (0.02 mg/kg, administered intramuscularly every 2 to 4 weeks until serum concentration normalizes).

Serum folate concentrations are high in about a third of dogs with EPI. This may indicate SIBO, although the sensitivity and specificity of high serum folate concentration for the diagnosis of SIBO is poor. The definition and diagnosis of SIBO is problematic, and it is better to assume that a newly diagnosed dog with EPI has SIBO and treat it appropriately than to rely on the results of diagnostic tests. The importance of SIBO in cats with EPI is unknown. Occasionally in dogs and cats with EPI, serum folate concentration

may be low; this can suggest either dietary deficiency or concurrent inflammatory or infiltrative disease in the jejunum. Unlike cobalamin, there is no clear evidence that folate should be supplemented in dogs when it is low.

# Treatment **DRUGS**

All dogs and cats with clinical EPI require enzyme supplementation for life. In most cases this is provided as a powder or in the form of a capsule, which is opened and then sprinkled on the food. Fresh raw pancreas (which can be frozen in aliquots) may be used as an alternative and can be very effective, but there is also the potential for acquiring gastrointestinal infections (such as Salmonella and Campylobacter). The dose of enzymes is initially as recommended by the manufacturer and then titrated to the individual. A large proportion of enzyme activity is lost in the acid pH of the stomach (up to 83% of lipase activity and 65% of trypsin activity). To overcome this, either the dose of enzymes given is increased or an H2 blocker is administered concurrently to increase gastric pH. Preincubating enzymes with the food is not indicated because they require the alkaline environment of the small intestine to work properly. In the long term it is often possible to decrease the dose of enzymes given (but not stop altogether). This may be due to resolution of the secondary bacterial overgrowth and the effects of chronic malnutrition and cobalamin deficiency on enterocytes and brush border enzymes. Reports suggest that enzyme replacement may be reduced over the long term by between 6% and 58% but not stopped altogether.

Dogs and cats with EPI and concurrent SIBO require courses of appropriate antibiotics (oxytetracycline, tylosin, or metronidazole). It is advisable to administer prophylactic medication for presumed SIBO in all newly diagnosed cases for 3 to 4 weeks in view of the high prevalence of concurrent bacterial overgrowth and the difficulty in diagnosing it, although it remains unclear whether initial antibiotic therapy improves prognosis.

Dogs and cats with documented hypocobalaminemia will require parenteral vitamin B<sub>12</sub> injections (0.02 mg/kg, administered intrumuscularly every 2 to 4 weeks until serum concentration normalizes). It is relatively common for German Shepherd Dogs with PAA to have concurrent inflammatory bowel disease, and this must also be addressed. Animals with EPI as a result of chronic pancreatitis may require insulin therapy for concurrent DM and other therapies for acute flare-ups, including analgesics, as outlined in the section on pancreatitis.

# DIET

Disruption of fat digestion is the most important feature of EPI. A low-fat food has therefore been traditionally recommended, but it may not contain enough calories to feed a large-breed dog (e.g., a German Shepherd Dog) effectively. Fat usually contributes a significant proportion of daily energy intake because it is more energy-dense than carbohydrates. In large-breed dogs with EPI and cachexia, weight

gain may be very difficult to achieve with a low-fat diet. There is no convincing evidence in the literature that longterm feeding of a low-fat diet improves outcome in dogs with PAA, although there is some evidence that it may result in faster resolution of clinical signs. However, high-fat diets (such as proprietary renal diets) should obviously be avoided. We therefore recommend that dogs with PAA be fed a normal to moderately fat-restricted, highly digestible diet with reasonable calorie density. The diet should also be low in fiber because fiber impairs the activity of pancreatic enzymes and soluble fiber may actually absorb pancreatic enzymes. Fiber may also reduce small intestinal absorption and activity of brush border enzymes. The proprietary veterinary diets marketed for gastrointestinal disease in dogs (e.g., Hill's ID, Royal-Canin Digestive low fat HF, and Eukanuba Intestinal or Dermatosis FP) fulfill these requirements and are recommended, at least for initial stabilization. In the long term, after the gut wall recovers, these dogs can be maintained on a normal fat level in most cases and can often return to their normal diet. In some individuals with PAA extra calories can be added to the diet between meals in the form of medium chain triglycerides, such as coconut oil. They should not be used in cats and should not be given in overly high doses in dogs because of the risk of osmotic diarrhea. The recommended daily amount is 1/4 to 4 teaspoons in dogs in divided doses. Medium chain triglycerides also cannot carry fatsoluble vitamins, will cause vomiting in some individuals, and are contraindicated in dogs with liver disease because they may worsen encephalopathy.

In dogs with EPI as a result of CP, dietary advice is slightly different. Many of these dogs benefit from long-term feeding of a low-fat diet, which seems to reduce postprandial pain and acute flare-ups of disease (Hill's ID; Royal-Canin Digestive low fat, or Eukanuba Intestinal). Therefore proprietary low-fat diets would be preferred in these patients. The use of medium chain triglycerides is not recommended in dogs with chronic pancreatitis, but fortunately these are often small-breed dogs with less cachexia than the German Shepherd Dogs with PAA.

It is best to feed two or more meals a day, each with enzymes added, and the dog should not be allowed to scavenge. This is often difficult because they are polyphagic, but scavenging, especially of fatty foods, causes recurrence of diarrhea and sets back recovery.

Cats with EPI are often best managed on a hypoallergenic intestinal type diet (e.g., Hill's DD, Eukanuba dermatosis LB, or Royal-Canin limited ingredient diets) because there is a high incidence of concurrent inflammatory bowel disease. If they are also diabetic, it is unclear whether they should be fed an intestinal diet or a proprietary feline diabetes diet (e.g., Hill's MD, Royal-Canin diabetic diet, or Purina DM).

#### **Prognosis**

The prognosis for dogs with EPI is good because the disease can be treated. However, a surprising number of dogs (19% in one recent study) are euthanized within the first year of treatment because of poor response to therapy (Batchelor et al., 2007b). The same study showed that the median survival time of dogs that responded to treatment was very good, at 1919 days. This underlines the importance of scheduling regular follow-up appointments, particularly in the initial stages of therapy, to evaluate progress and change management as necessary. Prognosis for dogs and cats with EPI as a result of end-stage chronic pancreatitis is surprisingly good in most cases, even if it is complicated by concurrent DM, with survival times of several years in most cases.

# **EXOCRINE PANCREATIC NEOPLASIA**

Neoplasms of the exocrine pancreas are uncommon in both cats and dogs. Pancreatic adenocarcinomas have a very aggressive biological behavior and have usually disseminated widely by the time of diagnosis. They are often subclinical until they have disseminated, but they can result in single or repeat bouts of pancreatitis and/or the development of EPI. Some pancreatic tumors have been associated with paraneoplastic syndromes such as sterile panniculitis in dogs, alopecia with shiny skin in cats, and hypercalcemia. Chronic pancreatitis is a risk factor for the development of pancreatic adenocarcinomas in humans, and this may also be true in dogs because the published reports of these tumors in dogs show a predominance of Cocker and Cavalier King Charles spaniels.

Pancreatic adenomas are rare in small animals but have been reported in cats. Nodular hyperplasia of the exocrine pancreas is also common in older dogs and cats. This usually presents as multiple small masses, whereas pancreatic tumors are usually single, but histopathology or cytology is necessary to definitively differentiate hyperplasia from neoplasia. Both dogs and cats with acute and chronic pancreatitis sometimes present with a large pancreatic "mass" as a result of fat necrosis and/or associated fibrosis, and it is important not to confuse these with neoplasia. Again, histopathology is required to differentiate these conditions. Ultrasound-guided fine needle aspiration cytology has been suggested as a useful means of differentiating inflammatory and neoplastic lesions of the pancreas (Bjorneby and Kari, 2002). Clinical use in dogs and cats is limited, but it has been reported to be helpful in diagnosis in some studies (Bennet et al., 2001).

Pancreatic tumors are not associated with any specific clinicopathological changes and may cause no changes in enzymes at all. Alternatively, they can result in recurrent bouts of pancreatitis with typical associated blood changes, and EPI can develop. In some cases biliary tract obstruction may occur with associated jaundice and marked elevations in liver enzyme activities. Occasionally, pancreatic tumors have been reported associated with marked hyperlipasemia.

The prognosis in dogs and cats with pancreatic adenocarcinoma is very poor. The tumors are extremely aggressive, poorly sensitive to chemotherapy or radiotherapy, and have usually disseminated widely by the time of diagnosis. Neuroendocrine tumors such as insulinomas and gastrinomas appear to be more common than pancreatic adenocarcinomas in dogs and tend to be seen in different breeds of dog, predominantly large breeds (Watson et al., 2007). These are tumors of the endocrine pancreas that produce clinical signs related to secretion of hormones and are therefore outside the scope of this chapter.

# PANCREATIC ABSCESSES, CYSTS, AND PSEUDOCYSTS

Pancreatic abscesses, cysts, and pseudocysts are uncommonly reported in dogs and cats and are usually a complication or sequela of pancreatitis. Pancreatic cysts may be congenital (e.g., as part of the polycystic renal disease in Persian cats) or secondary to cystic neoplasia, but the most common are pseudocysts secondary to pancreatitis. A pancreatic pseudocyst is a collection of fluid containing pancreatic enzymes and debris in a nonepithelialized sac. Pseudocysts have been recognized in association with pancreatitis in both cats and dogs, although they appear to be rare, and microscopic acinar cysts were found frequently in feline chronic pancreatitis. Pseudocysts are not associated with any distinct clinicopathological findings other than those associated with the underlying pancreatitis. Analysis of fluid obtained from a pseudocyst by fine needle aspiration generally shows a modified transudate. The activities of amylase and lipase can be measured in the pseudocyst fluid. In humans the enzymes are higher in pseudocysts associated with pancreatitis than in those associated with cystic carcinomas, but the value of this measurement in small animals is unknown. Cytology can differentiate a pseudocyst from a true abscess because a pseudocyst contains amorphous debris; some neutrophils and macrophages; and, rarely, small numbers of reactive fibroblasts, whereas an abscess contains many degenerative neutrophils and variable numbers of pancreatic acinar cells, which may appear very atypical as a result of inflammation.

A true pancreatic abscess is a collection of septic exudate that results from secondary infection of necrotic pancreatic tissue or a pancreatic pseudocyst. They are associated with a poor prognosis but fortunately are rare in dogs and cats.

Treatment of pancreatic pseudocysts can be surgical or medical. Medical treatment by ultrasound-guided cyst aspiration has had a reasonable success rate. Pancreatic abscesses should be treated surgically with omentalization or open peritoneal drainage. Both carry a high mortality rate, but a recent study suggested that omentalization may be preferable (Johnson et al., 2006).

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
ANALGESICS ANTIBACTERIALS		See Table 40-8
Amoxicillin and ampicillin	10-20 mg/kg PO, SC, or IV q8-12h dogs and cats	Broad-spectrum bactericidal and therapeutic levels in liver and bile Biliary tract infections; control of gut bacteria in hepatic encephalopathy; control of systemic infection of gut origin
Cephalexin	10-20 mg/kg PO, SC, or IV q8-12h dogs and cats	Preferably used on basis of culture and sensitivity Very similar activity and spectrum to ampicillin—see ampicillin Helpful in patients with penicillin hypersensitivity; <10% show cross-reaction to cephalexin
Enrofloxacin (Baytril)	5 mg/kg SC or PO q24h dogs and cats	Bactericidal particularly against gram negatives; poor efficacy against anaerobes and strep; good tissue penetration Bilary tract infections, particularly with gram-negative organisms Also infectious complications of pancreatitis Preferably used on basis of culture and sensitivity; should not be used in growing dogs (toxic to growing cartilage); used only with care in cats: risk
Marbofloxacin (Zeniquin)	2 mg/kg SC, PO, or IV q24h dogs and cats	of retinal damage As enrofloxacin
Metronidazole	10 mg/kg PO or slowly IV q12h dogs and cats  If significant hepatic functional impairment, reduce to 7.5 mg/kg q12h	Bactericidal particularly effective against anaerobes; often used in combination with ampicillin for biliary tract infections or to control gut bacteria in hepatic encephalopathy
Neomycin	20 mg/kg q6-8h PO or as a retention enema dogs and cats	Particularly used in acute hepatic encephalopathy; systemic absorption and oto- and nephrotoxicity can occur if there is concurrent GI ulceration, particularly in cats.
Potentiated sulphonamides, (e.g., trimethoprim-sulpha)	15 mg/kg of combined ingredients (trimethoprim + sulphonamide) PO q12h	Bactericidal, broad-spectrum and probably drug of choice with infectious complications of pancreatitis; should not be used in liver disease if possible because hepatotoxic in susceptible individuals; should not be used in Doberman Pinschers because of reduced hepatic clearance; immune-mediated diseases occasional adverse effects
ANTIEMETICS Chlorpromazine	0.2-0.4 mg/kg SC q8h dogs and cats	Indicated in vomiting associated with pancreatitis and some cases of hepatitis, but only if other antiemetics tried and ineffective because it is a phenothiazine sedative; effective antiemetic but also sedative, so ensure adequate hydration and avoid or use very low dose in encephalopathy and cardiovascular compromise
Metoclapramide	0.2-0.5 mg/kg PO or SC q8h or 1 mg/kg q24h as a constant rate infusion	Indicated in vomiting associated with liver disease and some cases of pancreatitis; however, peripheral prokinetic effect may increase pain in pancreatitis; neurological adverse effects occasionally seen; avoid in encephalopathy

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Maropitant (Cerenia)	Dogs only: 1 mg/kg SC q24h for up to 5 days or 2 mg/kg orally q24h for up to 5 days	Centrally acting antiemetic in new class [NK <sub>1</sub> receptor antagonist]; antiemetic of choice in canine pancreatitis as no obvious prokinetic effect; used with care in liver disease because metabolized in the liver, so do not use if significant liver dysfunction; not licensed for cats
Ondansetron (Zofran)	Cats and dogs: 0.5 mg/kg IV loading dose followed by 0.5 mg/kg/hour infusion q6h or 0.5-1 mg/kg PO q12-24h	Refractory vomiting; may be contraindicated in pancreafitis because it has been reported to trigger it in humans
ANTIENCEPHALOPATHIC	φ	
Lactulose	5-15 ml PO q8h (dogs) 0.25-1 ml PO q8h (cats) Can also be given as retention enema in acute encephalopathy See antibacterial section	Hepatic encephalopathy with acquired or congenital portosystemic shunts; overdose produces diarrhea; titrate to effect (= 2-3 soft bowel movements a day)
Antibiotics (e.g., ampicillin, metronidazole, neomycin)	See antibacterial section	
Propofol	Constant rate infusion; rate calculated by giving an initial bolus to effect (usually about 1 mg/kg) and timing duration of action; usually about 0.1-0.2 mg/kg/min	Drug of choice for seizures because of liver disease/ hepatic encephalopathy; should not be used in pancreatitis because it is a lipid vehicle
Phenobarbital	5-10 mg/kg PO q24h preoperatively followed by 3- 5 mg/kg q12h postoperatively for 3 weeks	Can be used prophylactically before and immediately after surgery to reduce risk of postoperative seizures after ligation of PSS, but evidence of effectiveness is anecdotal
ANTIINFLAMMATORY and ANTIFIBROTIC		• · · · · · · · · · · · · · · · · · · ·
Prednisolone (prednisone)	Antiinflammatory dose: 0.5 mg/kg q24h; immunosuppressive dose: 1-2 mg/kg q24h. Taper at 0.5 mg/kg q24h or eod	Antiinflammatory or immunosuppressive doses in lymphocytic cholangitis in cats and chronic hepatitis in dogs and in suspected immune-mediated pancreatitis in English Cocker spaniels  Avoid in suppurative cholangitis; avoid in portal hypertension or animals with ascites (potential GI ulceration); avoid use of dexamethasone because very ulcerogenic
Colchicine	Dogs only 0.03 mg/kg/day PO	Antifibrotic of choice in moderate hepatic fibrosis in dogs, but efficacy unclear; monitor blood samples for bone marrow suppression; GI side effects common and most likely reason to stop therapy
ANTIOXIDANTS		common and most many rousem to stop marapy
S-adenosylmethionine	Dogs: 20 mg/kg PO q24h or	Indicated in any liver disease but particularly hepatic
(SAM-e) (Denosyl)	higher; cats: 20 mg/kg or 200-400 mg total daily	lipidosis in cats and toxic hepatitis and diseases causing biliary stasis in dogs and cats; tablets must be given whole on an empty stomach for effective absorption
Sylmarin (silymarin, silibin)	50-200 mg/dog PO q24h	Antioxidant derived from milk thistle; likely effective and safe, but very limited studies to base dose advice on in dogs; studies were in toxic hepatitis
Vitamin E (tocopherol)	400 IU per day for medium-sized dogs (titrate accordingly for other sizes) or 5-25 IU/kg PO daily dogs and cats	Indications as SAMe but including any chronic hepatitis in dogs

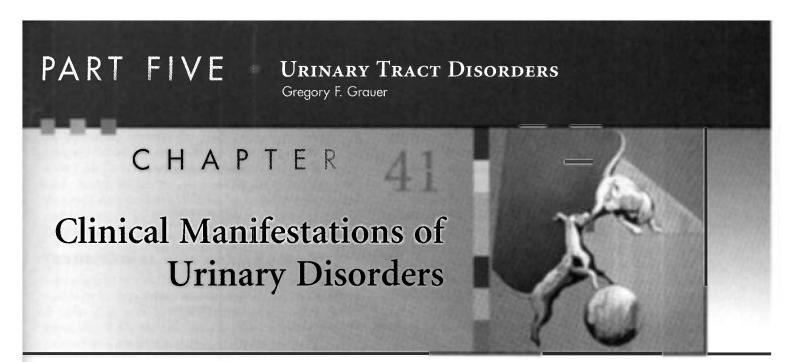

Drugs Used in Hepatobiliary and Pancreatic Disorders—cont'd

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Zinc (see copper chelating) and ursodeoxycholic acid (see choleretic) also have antioxidant activities ANTIDOTES		
N-acetylcysteine	Cats and dogs: 140 mg/kg IV or PO as a loading dose and then continued at 70 mg/kg q6h for a total of 7 treatments or for up to 5 days	Antidote for acetaminophen toxicity that binds the toxic metabolite and increases the glucuronidation process; can cause nausea and vomiting when given orally; foul taste makes oral dosing difficult without nasogastric tube
Cimetidine	Dogs: 5-10 mg/kg IV, IM, or PO q6-8h; Cats 2.5-5 mg/kg IV, IM, or PO q8-12h	Slows oxidative hepatic drug metabolism by binding to microsomal cytochrome P450; therefore useful additional antidote in acetaminophen toxicity in dogs and cats
Also antioxidants such as S-adenosylmethionine and vitamins E and C supportive for oxidant toxins such as acetaminophen ANTIULCER TREATMENT	See sections on antioxidants and vitamins	·
Ranitidine (Zantac)	2 mg/kg PO or slowly IV q12h dogs and cats	Acid secretory inhibitor of choice in liver disease; may not be necessary if gastric pH is high; Cimetidine should be avoided because of action on P450 enzymes, except as an antidote (see above)
Sucralfate (Carafate) COPPER CHELATING	Dogs: 1 g per 30 kg 4 times a day. Cats: 250 mg/cat PO q8-12h	Gastric ulceration associated with liver or pancreatic disease
Penicillamine	Dogs only: 10-15 mg/kg PO q12h	Copper chelator for copper storage disease; takes months to de-copper liver; give on an empty stomach; vomiting common; Immune-mediated, renal, and skin disease possible
2,3,2-tetramine tetrahydrochloride (2,3,2– T) and 2,2,2-tetramine tetrahydrochloride	Dogs only: 10-15 mg/kg PO q12h	Copper chelator for copper storage disease in dogs; more rapid effect than penicillamine so may be more useful in acute disease; 2,3,2-tetramine produces greater copper loss but is not available as a drug; isolated case reports of their use in dogs but no extensive trials; toxicity data unclear except that prolonged use may lead to clinical signs resulting from low copper levels
Zinc acetate or sulphate	1-20 mg/kg/day of elemental zinc dogs; 7 mg/cat/day of elemental zinc cats	Indicated in copper storage disease to reduce copper absorption; also antioxidant, antifibrotic, and increases ammonia detoxification, so may be helpful in any chronic hepatitis or hepatic encephalopathy; monitor blood levels every 1-2 weeks and keep below 200-300 µg/dl to avoid toxicity (iron deficiency and hemolysis); main side effect is vomiting—give 1 hour before food to minimize this
CHOLERETIC Ursodeoxycholic acid (Ursodiol)	4-15 mg/kg per day split into two doses 12 hours apart (dogs); 15 mg/kg PO once a day (cats)	Choleretic + also moderates bile acid pool to be less toxic + antiinflammatory and antioxidant; indicated in conditions associated with biliary stasis but without complete bile duct obstruction; contraindicated with obstruction in case of gallbladder rupture

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
DIURETIC		
Furosemide	2 mg/kg PO q8-12h dogs and cats	Use as additional divretic where necessary in ascites of liver disease; always use concurrent spironolactone to avoid compensatory increase aldosterone action with further water retention and hypokalaemia
Spironolactone	2-4 mg/kg day in divided doses dogs and cats	Diuretic of choice in ascites of liver disease (see text Chapter 39); Gradual onset of action over 2-3 days; may be combined with furosemide for more marked diuresis
TREATMENT OF COAGULOPATHIES		
Fresh frozen plasma	Dogs and cats: starting dose of 10 ml/kg; the dose of plasma is titrated based on the results of the OSPT and APTT	Replenish depleted clotting factors in severe acute or chronic liver disease, particularly if prolonged OSPT and/or APTT and no response to vitamin K treatment alone
Vitamin K1 (Phytomenadione) (Konakion)	0.5-2 mg/kg SC or IM 12 hours before biopsy and then q12h for 3 days	Treatment of coagulopathy associated with liver disease, particularly if concurrent biliary stasis and/ or gut disease reducing vitamin K absorption; treatment of coagulopathy before liver biopsy
VITAMINS		στο
Vitamin B <sub>12</sub> (Cyanocobalamin)	Dogs and cats: 0.02 mg/kg IM or SC every 2-4 weeks until serum concentration normalizes (oral dosing ineffective in EPI because of ineffective absorption)	Treatment of vitamin B <sub>12</sub> deficiency, particularly associated with EPI and lack of pancreatic intrinsic factor
Vitamin K1(Phytomenadione)	See treatment of coagulopathy section	
Vitamin E	See antioxidant section	
Vitamin C (ascorbic acid)	Cats and dogs oxidant toxins: 30-40 mg/kg SC q6h for 7 treatments	Indicated only as supportive treatment for oxidant toxins affecting the liver (e.g., acetaminophen)  Not indicated in other cases of hepatitis or copper storage disease because increases absorption and hepatic build-up of metals

PO, By mouth; SC, subcutaneous; IV, intravenous; GI, gastrointestinal; PSS, portosystemic shunt; IM, intramuscular; EPI, exocrine pancreatic insufficiency.

RENOMEGALY

# **GENERAL CONSIDERATIONS**

This chapter begins with a discussion of urinary tract problems that are likely to be identified by pet owners (e.g., pollakiuria and dysuria-stranguria, hematuria, urinary incontinence, and polydipsia and polyuria). Problems that are usually identified on the basis of a physical examination, a minimum database, or with imaging techniques, including proteinuria, azotemia, and renomegaly, are discussed subsequently.

# POLLAKIURIA AND DYSURIA-STRANGURIA

Lower urinary tract inflammation (LUTI) usually results in increased frequency of urination (pollakiuria) and difficult urination (dysuria) associated with straining (stranguria; Fig. 41-1). LUTI in dogs is often caused by bacterial infection; in contrast, primary bacterial infection of the urinary tract is relatively rare in cats. Sterile inflammation (e.g., some cases of calcium oxalate urolithiasis and idiopathic cystitis) or space-occupying masses of the lower urinary tract (e.g., neoplasia, ureterocele) can result in pollakiuria and dysuriastranguria in both dogs and cats. When an animal has clinical signs suggestive of LUTI or obstruction, transabdominal palpation of the bladder may confirm the presence of a distended bladder, a thickened bladder wall, a bladder mass, or urolithiasis. If possible, urinary bladder palpation should be performed before and after the patient voids because a full bladder may obscure the presence of intraluminal masses or uroliths. Digital rectal examination in smaller male and female dogs and in cats often allows the clinician to evaluate the trigone of the bladder and the pelvic urethra in a search for masses or uroliths. Urinalysis, urine bacterial culture, ultrasonography of the bladder, and/or plain or contrastenhanced radiography of the bladder and urethra often demonstrate the cause of the pollakiuria and dysuriastranguria; occasionally, advanced imaging modalities (e.g., computed tomography (CT) scan) may be necessary to evaluate the lower urinary tract. Currently, cystoscopy is widely used in specialty practices and academic hospitals for evaluation of patients with lower urinary tract diseases. If systemic signs (e.g., depression, lethargy, anorexia, vomiting) are present in animals with LUTI, a complete blood count (CBC) and serum biochemistry profile should also be obtained, and the kidneys, prostate, and uterus/uterine stump should be evaluated as a possible source of the signs.

# **URETHRAL OBSTRUCTION**

Urethral obstruction, either functional (e.g., reflex dyssynergia, urethral spasm) or anatomic (e.g., urolithiasis, granulomatous urethritis, neoplasia), usually causes pollakiuria, dysuria-stranguria, or both, with an attenuated or absent urine stream. A urethral catheter will pass relatively easily in

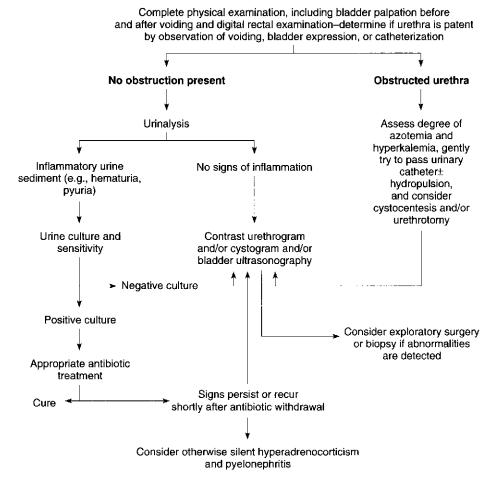

FIG 41-1 Diagnostic approach to pollakiuria and dysuria-stranguria (see also Fig. 41-7).

TABLE 41-1

Numbers of Bacteria per Milliliter Considered Significant According to Method of Urine Collection in Dogs and Cats

COLLECTION METHOD	SIGNIFICANT	QUESTIONABLE	CONTAMINATION
Cystocentesis	>1000	100 to 1000	<100
Catheterization	>10,000	1000 to 10,000	<1000
Voided or expressed	>100,000	10,000 to 100,000	<10,000

patients with a functional obstruction, whereas an anatomic obstruction will result in "grating," difficult passage or the inability to pass the catheter. If there is any question, a positive contrast retrograde urethrogram will confirm the presence of an anatomic lesion or obstruction. If a complete urethral obstruction exists, the degree of postrenal azotemia and hyperkalemia should be assessed immediately. Hyperkalemia can cause life-threatening cardiac arrhythmias and should be treated promptly (see Fig. 41-1).

#### URINARY TRACT INFECTION

Urine for urinalysis and bacterial culture may be obtained by antepubic cystocentesis, urinary bladder catheterization, or a midstream catch during voiding. However, the number of organisms isolated in a normal dog or cat varies according to the technique used (Table 41-1). Ideally, urine should be obtained by cystocentesis, and urine specimens should be plated within 30 minutes of collection. If this is not possible, the urine sample should be refrigerated in a closed container because bacteria may double their numbers in urine every 45 minutes at room temperature, resulting in false-positive culture findings. On the other hand, false-negative urine culture results may be obtained if the urine has been frozen or refrigerated for 12 to 24 hours or more.

Animals with recurrent or refractory urinary tract infections (UTIs) should undergo ultrasonography or contrast-

enhanced radiography in a search for underlying anatomic disorders. Bladder tumors or polyps, uroliths, pyelonephritis, prostatitis, ureteroceles, and urachal remnants are common causes of recurrent or unresponsive UTIs. In some cases, systemic disorders such as hyperadrenocorticism, chronic kidney disease, and diabetes mellitus may be associated with recurrent UTIs, as can long-term corticosteroid treatment. UTIs are discussed in greater depth in Chapter 45.

#### TRANSITIONAL CELL CARCINOMA

Transitional cell carcinoma (TCC) is the most common malignant bladder tumor in dogs and should be suspected in older dogs with hematuria, pollakiuria, and dysuriastranguria. TCCs are rare in cats, where they are usually detected as a diffuse thickening of the bladder wall during palpation or imaging. TCCs most frequently arise in the bladder trigone region; therefore rectal palpation can often detect their presence. Urinary bladder ultrasonography or double contrast-enhanced cystography will confirm that a bladder mass exists. In some cases, unilateral or bilateral hydroureter-hydronephrosis is observed as a result of obstruction of one or both ureters at the vesicoureteral junction. Tumor biopsy and histopathologic evaluation should be done to confirm the tumor type and stage and to direct the nature of specific treatment. The bladder tumor antigen test (V-BTA test: www.polymedco.com) is usually not recommended as a diagnostic aid because it does not reliably differentiate dogs with bladder cancer from dogs with LUTI resulting from other causes. In some specialty practices, cystoscopy provides a simple method to obtain a diagnostic sample for histopathology and assess the extent of bladder involvement in dogs and cats with infiltrative bladder diseases.

# **UROLITHIASIS**

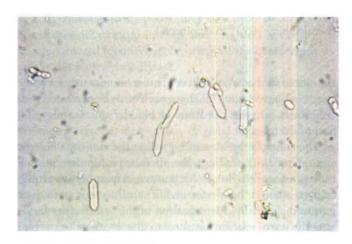

Urinary bladder and urethral uroliths can often be palpated during abdominal or rectal examination; however, a full bladder or a thickened, inflamed bladder wall may obscure small uroliths. In male dogs with dysuria, the urethra should be palpated subcutaneously from the ischial arch to the os penis in a search for urethral uroliths. Ultrasonography or plain or contrast-enhanced radiography of the urinary tract may be necessary to confirm the presence of uroliths. Calcium oxalate and struvite uroliths are the most radiodense, whereas urate uroliths are relatively radiolucent, and contrast-enhanced radiographs may be required for their diagnosis. Silicate and cystine uroliths have an intermediate radiodensity, and unless the stones are small (<5 mm in diameter), they can usually be observed on plain film radiographs.

Urinalysis findings in dogs and cats with urolithiasis often indicate the presence of urinary tract inflammation (e.g., hematuria, pyuria, increased numbers of epithelial cells, and proteinuria). The urine pH varies depending on the stone type, on the presence or absence of a concurrent bacterial infection, and on the animal's diet. In general, struvite uroliths are associated with an alkaline urine (especially if

urease-producing bacteria are present); cystine uroliths with an acidic urine; and oxalate, urate, and silicate uroliths with a neutral-to-acidic urine. Crystalluria may be observed depending on the urine concentration, pH, and temperature. Although crystalluria may exist in the absence of uroliths, and uroliths may be present in the absence of crystalluria, if the two coexist, the identity of the crystals is usually the same as that of the urolith (Figs. 41-2 to 41-6). Exceptions do occur, however; for example, a urease-producing bacterial infection could generate struvite crystals in the presence of silicate or calcium oxalate uroliths. Bacterial urine culture and sensitivity testing should be performed in all animals with urolithiasis to identify and properly treat any concurrent UTI. If a cystotomy is performed to remove stones, a small piece of the bladder mucosa or urolith should be

FIG 41-2

submitted for bacterial culture. This is because urine may be sterile in dogs and cats that have previously been treated with antibiotics, whereas the stone or bladder mucosa may still harbor bacteria.

The animal's signalment, as well as the clinicopathologic and radiographic findings, are often helpful in determining the type of urolith (Box 41-1); however, a quantitative urolith analysis should be performed if uroliths are passed or removed surgically. Identification of the urolith type facilitates the use of specific measures to dissolve them or prevent their recurrence. Qualitative commercial kit analysis of uroliths is not recommended because these kits do not detect silicic acid salts, frequently fail to detect calcium-containing uroliths, and yield false-positive results for uric acid more than half of the time in animals with cystine uroliths. Quan-

titative urolith analysis, available at most teaching hospitals and reference laboratories, is recommended instead.

Urolithiasis is discussed in greater detail in Chapters 46 and 47.

# FELINE LOWER URINARY TRACT DISEASE (LUTD)

Cats with LUTD (often referred to as feline urologic syndrome, feline lower urinary tract inflammation, or feline interstitial cystitis; see Chapter 47) usually are presented because of pollakiuria, dysuria-stranguria, microscopic or gross hematuria, or inappropriate voiding. In male cats with a urinary tract obstruction, the presenting signs depend on how long the obstruction has been present. Within the first 6 to 24 hours, most obstructed cats will make frequent attempts to urinate, pace, vocalize, hide under beds or behind couches, lick their genitalia, and display anxiety. If the obstruction is not relieved within 36 to 48 hours, characteristic clinical signs of postrenal azotemia and hyperkalemia, including anorexia, vomiting, dehydration, depression, weakness, collapse, stupor, hypothermia, acidosis with hyperventilation, or bradycardia, may be observed. Sudden death may also occur.

On physical examination an unobstructed cat is apparently healthy, except for a small, easily expressible bladder. The bladder wall may be thickened, and palpation may cause the animal to void. Abdominal palpation may be painful to the unobstructed cat; however, the obstructed cat will always resent manipulation of the caudal abdomen unless it is severely depressed or comatose. The most significant physical examination finding in an obstructed cat is a turgid, distended bladder that is difficult or impossible to express. Care should be exercised in manipulating the distended bladder, however, because the wall has been injured by the increased intravesical pressure and is susceptible to rupture. In a male cat with a urethral obstruction, the penis may be

BOX 41-1

# Factors That May Aid in the Identification of Uroliths in Dogs

#### Struvite

- 80% to 97% of uroliths in female dogs are struvite.
- Uroliths in dogs younger than 1 year of age are usually struvite.
- There is a high incidence of concurrent urinary tract infection (especially Staphylococcus or Proteus spp.).
- · Urine is usually alkaline.
- Uroliths are radiodense.
- Increased prevalence in Miniature Schnauzers, Miniature Poodles, Bichon Frises, Cocker Spaniels.

#### **Calcium Oxalate**

- Increased prevalence in older male dogs (especially Miniature Schnauzers, Miniature Poodles, Yorkshire Terriers, Lhasa Apsos, Bichon Frises, and Shih Tzus).
- Urine is usually acidic to neutral.
- Uroliths are radiodense.
- Hypercalcemia may be a contributing factor.

#### **Ammonium Acid Urate**

Increased prevalence in male dogs (especially Dalmatians and Bulldogs).

- Urine is usually acidic to neutral.
- Uroliths are relatively radiolucent.
- Increased incidence in dogs with severe hepatic insufficiency (e.g., portosystemic shunts in Miniature Schnauzers and Yorkshire Terriers).

#### Silicate

- Increased prevalence in male dogs (especially German Shepherd Dogs, Golden Retrievers, and Labrador Retrievers).
- · Urine is usually acidic to neutral.
- Urolith radiodensity is variable.
- High dietary intake of silicates probably predisposes (corn gluten and soybean hulls).

#### Cystine

- Increased prevalence in male dogs (especially Dachshunds, Basset Hounds, Bulldogs, Yorkshire Terriers, Irish Terriers, Chihuahuas, Mastiffs, and Rottweilers).
- Urine is usually acidic.
- Urolith radiodensity is variable.

congested and it may protrude from the prepuce. Occasionally, a urethral plug is seen extending from the urethral orifice, and in some cases the cat may lick its penis until it becomes excoriated and bleeds.

A history of acute onset of pollakiuria, dysuriastranguria, and hematuria in an otherwise healthy cat indicates LUTD. Physical examination should include digital rectal palpation of the caudal bladder and urethra in an attempt to determine whether there are masses or calculi, as well as abdominal palpation of the bladder before and after voiding to determine the residual urine volume and whether there are intraluminal masses or uroliths. The minimal diagnostic workup in cats with pollakiuria and dysuria-stranguria should always include a complete urinalysis. The urine should preferably be obtained by cystocentesis; however, if manipulation of the bladder during abdominal palpation results in voiding, a sample obtained from a clean tabletop may be used to assess urine pH and sediment.

An extensive diagnostic evaluation of the unobstructed cat is usually not warranted. In most of these cases the urine is bacteriologically sterile, and clinical signs respond to canned food dietary therapy. However, if clinical signs persist beyond 5 to 7 days of instituting dietary therapy, a second urinalysis with a urine culture and sensitivity, radiography of the abdomen, ultrasonography, and/or contrast-enhanced cystography-urethrography should be performed (Fig. 41-7).

# **HEMATURIA**

Hematuria, the presence of red blood cells in the urine, is frequently encountered in clinical veterinary medicine.

Because the urine strip reagents detect hemoglobin and myoglobin, a positive "blood" test in a urine dipstick does not necessarily mean that the patient has hematuria, and the sediment should be evaluated microscopically (discussed in more detail later). Hematuria occurring in conjunction with pollakiuria and dysuria-stranguria is usually associated with LUTI. Conversely, hematuria that occurs in the absence of other clinical signs often originates from the upper urinary tract. Hematuria may be gross (macroscopic hematuria) or occult (microscopic hematuria). Occult hematuria (more than five red blood cells per high-power field) is often present in dogs and cats with pollakiuria and dysuria-stranguria. The diagnostic workup in dogs and cats with hematuria is directed toward identifying the origin of the hemorrhage as well as the underlying disease.

In most cases hematuria is caused by inflammation, trauma, or neoplasia of the urogenital tract; however, hematuria may also be caused by systemic bleeding disorders, strenuous exercise, heat stroke, or renal infarcts. The renal telangiectasia that occurs in Cardigan Welsh Corgis may also cause hematuria, as can the renal hematuria in Weimaraners. The timing of gross hematuria during voiding may provide clues as to the source of the hemorrhage. Hematuria that occurs at the beginning of voiding (initial hematuria) is suggestive of hemorrhage originating from the lower urinary tract (bladder neck, urethra, vagina, vulva, penis, or prepuce). Extraurinary causes such as proestrus, metritis, pyometra, prostatic disease, or neoplasia of the genital tract may also cause initial hematuria (Table 41-2). Hematuria that occurs at the end of voiding (terminal hematuria) usually results

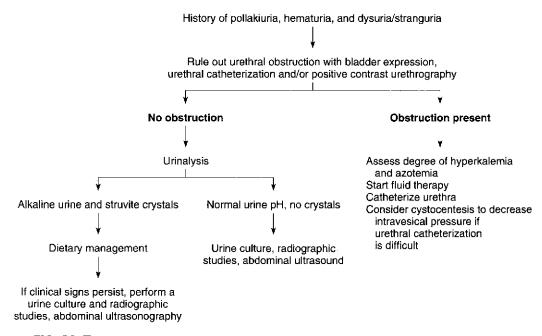

FIG 41-7
Diagnostic plan for feline lower urinary tract inflammation syndrome.

# Potential Causes of Hematuria

## **URINARY CAUSES**

# **EXTRAURINARY CAUSES**

# Initial hematuria

Urethral causes

Trauma Infection Urolithiasis

Neoplasia

Granulomatous urethritis Bladder trigone region

Neoplasia

Spontaneous bleeding unassociated with voiding may also occur with the following:

Prostatic: infection, cyst, abscess, tumor

Uterine: infection, tumor, proestrus, subinvolution

Vaginal: tumor, trauma

Preputial/penile: tumor, trauma

### Total or terminal hematuria

Pseudohematuria

Kidney, ureter, bladder

Infection Urolithiasis Tumor Parasitism

Trauma

Drug induced (cyclophosphamide)

Feline lower urinary tract inflammation syndrome

Renal infarct
Renal telangiectasia
Idiopathic renal hematuria

Prostatic (see above) Bleeding disorders Heat stroke Exercise-induced

from hemorrhage originating from the upper urinary tract (bladder, ureters, or kidneys). In this case the hemorrhage may be intermittent, which allows the red blood cells to settle in the bladder and be expelled with the last of the bladder contents. If hematuria occurs throughout voiding (total

hematuria), the hemorrhage usually originates in the bladder, ureters, or kidneys. Pseudohematuria may be caused by myoglobin or hemoglobin, drugs, and natural or artificial food dyes in the urine. In cases of pseudohematuria, the urine supernate remains discolored after centrifugation.

In dogs and cats with hematuria caused by inflammation, trauma, or neoplasia of the lower urinary tract, concurrent clinical signs usually include pollakiuria and dysuriastranguria. Hematuria associated with upper urinary tract disease may be associated with systemic signs, including depression, lethargy, anorexia, vomiting, diarrhea, weight loss, and abdominal pain, or it may be asymptomatic. In some cases upper urinary tract hemorrhage can result in the formation of blood clots in the bladder, leading to subsequent dysuria-stranguria. If hemorrhage from the genital tract is causing hematuria, spontaneous bleeding not associated with voiding may also be observed. Additional signs indicating that the genital tract is the source of hemorrhage include a purulent vaginal or urethral discharge independent of voiding, behavioral changes (e.g., proestrus), or straining to defecate in association with a stilted gait (e.g., prostatic

A complete physical examination often helps localize the source of the hematuria. If possible, the kidneys should be palpated and assessed in terms of their size, shape, consistency, and symmetry and for the presence of pain. The urinary bladder should be palpated before and after voiding, because, as already noted, a full bladder may obscure intraluminal masses, uroliths, or wall thickening. Observation of voiding should also be part of the physical examination and provides the opportunity to obtain a voided urine sample (Fig. 41-8). In addition, the timing of the hematuria can be confirmed and the character of the urine stream, as well as the presence or absence of dysuria, can be noted. Rectal palpation allows evaluation of the prostate in male dogs and of the pelvic urethra in dogs and cats of both sexes. The trigone region of the bladder can also be palpated rectally in small dogs and cats; this is facilitated by concurrent abdominal palpation, with the examiner pushing the bladder toward

the pelvic inlet. In larger female dogs digital vaginal palpation and the use of a vaginal speculum or scope allow for the urethral orifice to be evaluated; vaginal masses, strictures, and lacerations can be ruled in or out in this way. In male dogs the perineal urethra should be palpated subcutaneously from the ischial arch to the os penis, and the penis should be extruded from the prepuce and examined to determine whether there are masses, signs of trauma, or urethral prolapse. Finally, catheterization of the urethra in dysuric animals allows assessment of urethral patency; when indicated, positive contrast retrograde urethrography or ultrasonography can be employed to outline urethral anatomic abnormalities.

Comparison of urine obtained by cystocentesis with voided urine may help differentiate lower urinary tract or genital tract disease from upper urinary tract disease. Cystocentesis prevents the urine from being contaminated with bacteria, cells, and debris from the urethra, vagina, vulva, prepuce, or uterus; however, prostatic disease may alter the characteristics of urine obtained by cystocentesis (as a result of the reflux of fluid into the bladder). Abnormal urinalysis findings in urine collected by cystocentesis indicate involvement of the bladder, ureters, kidneys, or prostate. It should be remembered, however, that catheterization or bladder expression, and to a greater extent cystocentesis, may result in traumatic microscopic hematuria.

Urinalysis should be performed as soon as possible after urine collection. In addition to evaluating the urine sediment for red blood cells, the clinician should look for white blood cells, epithelial cells, tumor cells, casts, crystals, parasite ova, and bacteria. If urine remains at room temperature for more than 30 minutes, urease-producing bacteria can proliferate, resulting in an increase in the urine pH, which may cause red and white blood cells and casts to fragment

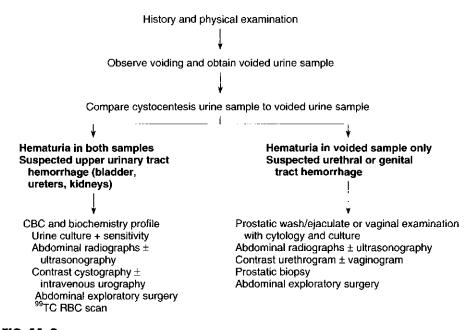

FIG 41-8

Diagnostic approach to dogs and cats with hematuria.

and lyse and may alter the crystal composition. In addition, hyposthenuria can result in the lysis of red and white blood cells, and lysed red blood cells in urine may create confusion between hemoglobinuria and hematuria. Refrigeration is the easiest way to preserve the stability of a urine sample. Although overnight refrigeration in a closed sterile container is acceptable for urine to be used for bacterial culture samples, it is not recommended for urine intended for chemical and cellular analysis.

Reagent strips used to detect blood in urine do so by detecting the peroxidase-like activity of hemoglobin from lysed cells. The test can detect approximately 0.05 to 0.3 mg of hemoglobin per deciliter of urine (equivalent to 10,000 lysed red blood cells per milliliter of urine, or approximately three lysed red blood cells per high-power field). These reagent test strips also show a positive reaction for blood in the presence of myoglobinuria.

A CBC and scrum biochemistry profile should be evaluated in dogs and cats with hematuria and concurrent systemic signs. An inflammatory leukogram is compatible with metritis-pyometra, acute bacterial pyelonephritis, or prostatitis. Azotemia occurring in association with hematuria usually indicates the presence of renal parenchymal disease or a rent in the urinary excretory pathway; however, prerenal causes of azotemia should also be ruled out. If the blood loss caused by hematuria is severe or if signs of generalized bleeding exist, a hemostasis profile, platelet count, and bleeding time should be evaluated (see Chapter 87).

Plain and contrast-enhanced radiography, ultrasonography, and/or cystoscopy will often help show the location and cause of hematuria. In some cases, abdominal exploratory surgery and biopsy may be necessary to arrive at a diagnosis. Biopsy specimens may be obtained from the kidneys, bladder, and prostate gland; if indicated, individual urcteral catheterization through a cystotomy or visualization through a cystoscope may be performed to determine if renal hematuria

is unilateral or bilateral. Nuclear medicine (technetiumlabeled red blood cells) can also be used to localize renal hematuria to one individual kidney.

# DISORDERS OF MICTURITION

Disorders of micturition include both urine retention and urine leakage (incontinence). Incontinence, the inappropriate passage of urine, may be caused by congenital abnormalities or acquired disorders. In evaluating an animal with incontinence, the clinician may find it helpful to determine whether the urinary bladder is distended, small, or normal in size (Table 41-3). Distended bladders are associated with urine retention and are usually caused by either detrusor hypocontractility or increased outflow resistance. Increased outflow resistance may be anatomic (e.g., urethral urolith) or functional (e.g., reflex dyssynergia). Urinary incontinence will occur with a primary urine retention disorder when intravesicular pressure overcomes outflow resistance pressure. This type of incontinence is termed paradoxic. More commonly, however, incontinence is associated with a small or normal-sized bladder that is typically caused by either decreased outflow resistance or increased detrusor contractility.

#### **Initial Evaluation**

The age of onset, reproductive status, age at neutering, current medications, and history of trauma or previous urinary tract disorders are important anamnestic points to cover when obtaining the history in an animal with disorders of micturition. The physical examination should include an evaluation of the perineum for evidence of urine scalding or staining. Thorough palpation of the bladder to assess its size and wall thickness and a rectal examination to assess anal tone, the prostate gland, the pelvic urethra, and the trigone region of the bladder should be performed in all cases. A

TABLE 41-3

Causes of Urinary Incontinence and Associated Clinical Signs

DISORDERS	CLINICAL SIGNS
Large bladder	
Lower motor neuron lesions	Dribbling of urine; distended bladder that is easily expressed; history of trauma or surgery in pelvic region
Upper motor neuron lesions	Distended bladder that is difficult to express; possible presence of paresis or paralysis
Reflex dyssynergia	Often, large-breed male dog; distended bladder that is difficult to express but easy to catheterize; urine stream initiated and then interrupted
Outflow tract obstruction	Usually male animals; dysuria-stranguria, dribbling of urine; distended bladder that is
Small bladder	difficult to express and catheterize
Urethral sphincter mechanism incompetence	Middle-aged or older neutered or spayed dogs; dribbling of urine usually occurring when animal is relaxed or asleep, normal voiding otherwise
Detrusor hyperreflexia/instability	Pollakiuria, dysuria-stranguria, hematuria, bacteriuria
Congenital abnormalities	Young animal; constant dribbling of urine possible, voiding possibly normal otherwise

digital vaginal examination is indicated, and vaginoscopy may be used to help identify congenital defects (e.g., vaginal strictures, ectopic ureters) in female dogs.

A neurologic examination should include evaluation of the perineal and bulbospongiosus reflexes. The perineal reflex causes the anal sphincter to contract and the tail to ventroflex in response to pinching of the perineal skin. The bulbospongiosus reflex causes the anal sphincter to contract in response to gentle compression of the bulb of the penis or the vulva. Both of these reflexes are dependent on an intact pudendal nerve (sensory and motor) and intact sacral spinal cord segments S1-S3. If both reflexes are normal, the pudendal reflex arc is intact. Because the pelvic nerve (sensory and motor parasympathetic innervation to the detrusor muscle) arises from the same sacral cord segments, damage to the pudendal nerve may also affect the pelvic nerve.

Dogs should be walked outside so that the voiding posture and urine stream size and character can be observed. Immediately after the animal has attempted to void, the bladder should be palpated to estimate the residual volume (normal residual volume is approximately 0.2 to 0.4 ml/kg). Catheterization to quantify the residual volume is indicated if a large bladder is palpable after voiding (in male dogs behavioral urine marking can make it difficult to assess the true residual urine volume).

A urinalysis should be performed in all animals with urinary incontinence. If a bacterial urine culture is indicated, as noted earlier, cystocentesis is the preferred method of collection; however, dogs and cats with a distended bladder should ideally be catheterized to empty the bladder and prevent the possibility of urine from leaking from the cystocentesis site.

# **Pharmacologic Testing and Treatment**

Frequently, the diagnosis of disorders of micturition (see Chapter 48) is based to some degree on the animal's response to pharmacologic testing and therapy. For example, detrusor hypocontractility should improve in response to a parasympathomimetic drug such as bethanechol, and urethral hypotonicity should respond to  $\alpha$ -adrenergic agents such as phenylpropanolamine or hormone replacement therapy. Urethral hypertonicity is treated with  $\alpha$ -sympatholytics (e.g., phenoxybenzamine) and striated muscle relaxants (e.g., diazepam). Detrusor hypercontractility often responds to treatment of the underlying inflammatory process (e.g., bacterial cystitis or urolithiasis); however, smooth muscle antispasmodics (e.g., oxybutynin) and parasympatholytics (e.g., propantheline) may be useful in cases of severe inflammation.

## DISTENDED BLADDER

Causes of incontinence that are typically associated with a distended bladder include neurogenic disorders (lower and upper motor neuron lesions and reflex dyssynergia) and urine outflow tract obstructive disorders (paradoxic incontinence; see Table 41-3). If neurologic lesions or deficits are detected during a neurologic examination, the status of the

bladder helps localize the lesion and classify the injury as an upper motor neuron (UMN) lesion (located above the fifth lumbar vertebral body) or a lower motor neuron (LMN) lesion (located at or below the fifth lumbar vertebral body). The most characteristic sign of an LMN lesion to the bladder is a distended bladder that is easily expressed. An LMN injury affecting innervation to the bladder creates both sphincter and detrusor hyporeflexia; if the lesion involves the S1-S3 spinal cord segments, both perineal and bulbospongiosus reflexes are absent.

Animals with UMN lesions to the bladder characteristically have a large, distended bladder that is difficult to express; the UMN lesion may also cause paresis or paralysis. Animals with a UMN lesion have no voluntary control of micturition, and the urethral sphincter shows reflex hyperexcitability because there is a lack of inhibition to the somatic efferents in the pudendal nerve, making expression of the bladder difficult. With time, UMN bladders may develop reflex contraction and partial emptying in response to detrusor stretching. This "automatic" emptying occurs without control or sensation.

Reflex dyssynergia or detrusor-urethral dyssynergia is a condition observed primarily in large-breed male dogs. The cause is usually difficult to determine but may include any of several neurologic lesions of the spinal cord or autonomic ganglia. Reflex dyssynergia results from active contraction of the detrusor without relaxation of the internal or external urethral sphincters. Characteristic signs of reflex dyssynergia include a normal or near-normal initiation of voiding, followed by a narrowed urine stream. Urine may be delivered in spurts, or flow may be completely disrupted and the animal will often strain to produce urine. After a while, the dog lowers his leg and then often begins dribbling urine as he walks away. Although it is difficult to express urine from the bladder of a dog with reflex dyssynergia, urethral catheterization is usually easy.

Incontinence in an animal with urinary outflow tract obstruction is called *paradoxic incontinence*. It occurs because intravesical pressure exceeds the pressure within the urethra, allowing urine to leak past the obstruction before a urethral or bladder rupture occurs. Clinical signs associated with an anatomic urethral obstruction include dribbling of urine, straining to urinate without producing urine, restlessness, and abdominal pain. The most common causes of urethral obstruction are calculi and neoplasia in dogs and urethral plugs in cats; however, urethral strictures and granulomatous urethritis can also create obstructions to urine flow. Prostatic disease in dogs may cause an outflow tract obstruction. Older male dogs with benign prostatic hyperplasia may be evaluated because of stranguria and tenesmus; however, prostatic neoplasia and prostatic abscess formation are more likely causes of urinary outflow tract obstruction in such animals.

# SMALL OR NORMAL-SIZED BLADDER

Causes of urinary incontinence in animals with a small or normal-size bladder include urethral sphincter mechanism incompetence (USMI), detrusor hyperreflexia or instability, and congenital abnormalities. Estrogen and testosterone are believed to contribute to the integrity of urethral muscle tone by increasing its responsiveness to  $\alpha$ -adrenergic innervation. Thus middle-aged to older, spayed female dogs are prone to the development of incontinence associated with decreased estrogen concentrations. This incontinence is most pronounced when the animal is asleep or relaxed and often responds to estrogen replacement therapy. Less frequently, incontinence develops in male dogs after castration; the condition seems to occur most commonly in dogs castrated at an older age and often responds to intramuscular testosterone administration. Diagnosis of both processes is based on the history, physical examination, and urinalysis findings (no evidence of LUTI) and on the response to therapy. Frequently, \alpha-adrenergic treatment (e.g., phenylpropanolamine) is effective in both male and female dogs with USMI incontinence, and in severe cases may be combined with hormone replacement treatment. Testosterone treatment is contraindicated in dogs that were neutered because of behavioral, prostatic, or perineal problems. In these cases  $\alpha$ -adrenergic treatment should be used; α-adrenergic treatment should be used with caution (or not at all) in patients wih hypertension.

Detrusor hyperreflexia or instability is the inability to control voiding because of a strong urge to urinate. Inflammation of the bladder or urethra may create a sensation of bladder fullness, which triggers the voiding reflex. Clinical signs of this type of incontinence include pollakiuria, dysuria-stranguria, and frequently hematuria. Bacterial UTI is the most common cause in the dog, and sterile LUTD is the most common cause in cats. A urinalysis that reveals evidence of UTI or inflammation (e.g., bacteriuria, pyuria, or hematuria) initially supports a tentative diagnosis of urge or inflammatory incontinence. If clinical signs persist after appropriate treatment for the urinary tract inflammation has been initiated, further diagnostic testing, including ultrasonography, contrast-enhanced radiography, and/or cystoscopy, are indicated because infiltrative disease of the bladder (e.g., neoplasia, chronic cystitis), polyps, uroliths, or urachal remnants can also result in pollakiuria and stranguria. It should also be noted that detrusor hyperreflexia/instability may also be a primary or idiopathic disorder that is not associated with bladder or urethral inflammation.

Urinary incontinence in a young animal may be associated with a variety of congenital defects of the urinary and genital systems. The most common defects are ectopic ureters and vaginal strictures, but a patent urachus, urethrorectal and urethrovaginal fistulas, and female pseudohermaphroditism have also been associated with urinary incontinence. Ectopic ureters are most commonly observed in female dogs. Breeds at high risk for ectopic ureters include Siberian Huskies, Miniature and Toy Poodles, Labrador Retrievers, Smooth Fox Terriers, West Highland White Terriers, Collies, and Cardigan Welsh Corgis. Ectopic ureters are rarely seen in cats, but the gender predisposition is reversed; the prevalence is higher in males than in females.

The most common clinical sign in an animal with ectopic ureters is a constant dribbling of urine, although dogs and cats with a unilateral ectopic ureter may void normally. Because 70% of ectopic ureters in dogs terminate in the vagina, vaginoscopy may allow visualization of the opening of the ectopic ureter; however, the opening can be difficult to see, even if the vagina is fully distended with air. Intravenous urography, retrograde vaginourethrography, and cystoscopy are additional diagnostic tests for characterizing the defect. In contrast to the incontinence associated with ectopic ureters, that associated with a vaginal stricture is often intermittent, occurring with changes in body position. Vaginal strictures can be diagnosed using digital vaginal examination, vaginoscopy, or contrast-enhanced vaginography.

Incontinence may also be caused by cognitive dysfunction, decreased bladder capacity, or decreased mobility in senior animals. Polyuric-polydipsic disorders such as chronic kidney disease and diabetes mellitus in senior animals also often exacerbate incontinence. Likewise, diuretic and corticosteroid therapy should be avoided in incontinent animals because of their negative effects on urine concentration.

#### POLYDIPSIA AND POLYURIA

Increased thirst and urine production are frequent presenting complaints in small animals. Polydipsia (PD) and polyuria (PU) in the dog and cat have been defined as a water consumption greater than 80 to 100 ml/kg/day and a urine production greater than 40 to 50 ml/kg/day, respectively. However, it is possible for thirst and urine production to be within the normal range and yet be abnormal in individual animals. Polydipsia and polyuria usually co-exist, and determining the primary component of the syndrome is one of the initial diagnostic considerations in an animal showing increased water consumption and urine production.

Thirst is stimulated primarily by osmotic factors. Hyperosmolality of the extracellular fluid usually occurs secondary to water loss, or it may result from the ingestion or intravenous infusion of hypertonic solutions. This hyperosmolality results in the dehydration of osmoreceptors, which stimulate thirst. Nonosmotic factors, including decreased arterial blood pressure, increased body temperature, pain, and certain drugs, can also stimulate thirst. Thirst is inhibited by expansion of the extracellular fluid volume, increased arterial blood pressure, drinking, and fullness of the stomach. Thirst is abnormally stimulated in animals with primary polydipsia, resulting in water consumption that exceeds physiologic need. Renal function in these animals is usually normal, and secondary polyuria occurs to rid the body of the excess water.

The kidneys maintain body fluid composition and volume by resorbing water and solutes from the glomerular filtrate. The resorption of solute in excess of water results in the formation of dilute urine. Conversely, the resorption of water in excess of solute results in the formation of concentrated urine. For concentrated urine to form, antidiuretic hormone (ADH) must be produced and released, and the renal tubules must be responsive to the ADH. For the latter to occur, the renal medullary interstitium must be hypertonic and at least one third of the total nephron population must be functional. ADH is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus and is stored in the posterior pituitary gland. Its release is stimulated by the same factors that stimulate thirst. In the presence of ADH, the distal portion of the distal convoluted tubule and the collecting duct become permeable to water, and water is resorbed from the tubular lumen. The hypertonicity of the renal medullary interstitium produces the osmotic pressure that drives the water resorption. A primary polyuria associated with a relative or absolute lack of ADH is termed central or pituitary diabetes insipidus (CDI), whereas a polyuria caused by nonresponsiveness to ADH is termed nephrogenic diabetes insipidus (NDI; Box 41-2).

Even though PU and PD usually occur together, the owner may not be aware of one or both components, depending on their severity and how closely the animal is observed. Conversely, owners frequently confuse pollakiuria with polyuria. Polyuria is often manifested by nocturia, pollakiuria and incontinence, whereas polydipsia is often manifested by a constantly empty water bowl and drinking from unusual sources, including toilets and puddles, and eating snow. It is relatively easy for most pet owners to measure 24-hour water consumption in a single-pet household, and this is a good way to confirm the presence of polydipsia; measuring water consumption in a multipet household is relatively difficult, unless the patient can be isolated.

A complete history and physical examination may suggest the underlying cause in animals with polydipsia and polyuria (Fig. 41-9); these include lymphadenopathy in dogs (lym-

phoma with hypercalcemia); perineal mass (anal sac adenocarcinoma with hypercalcemia); cataracts (diabetes mellitus); symmetric truncal alopecia (hyperadrenocorticism); vaginal discharge (pyometra); and small, irregular kidneys (chronic kidney disease). A minimum workup consisting of a CBC, serum biochemistry profile, urinalysis, thoracic radiography, and abdominal radiography or ultrasonography may confirm or suggest a diagnosis in many animals with primary polyuria (e.g., hypercalcemia and mediastinal lymphadenopathy in dogs with lymphoma or increased serum alkaline phosphatase activity in dogs with hyperadrenocorticism). Frequently, further specific tests are necessary to confirm a diagnosis (e.g., lymph node aspiration or biopsy for lymphoma and an ACTH-stimulation test for hyperadrenocorticism [Table 41-4]).

The urine specific gravity may also be helpful in determining the underlying cause of the syndrome and in confirming whether the pet is actually polyuric. Urine specific gravity is usually divided into four ranges: hyposthenuric urine has a specific gravity of between 1.001 and 1.007; isosthenuric urine has the same specific gravity as plasma, 1.008 to 1.012; minimally concentrated urine has a specific gravity of between 1.013 and 1.030 in dogs and 1.013 and 1.035 in cats; and hypersthenuric urine has a specific gravity of more than 1.030 in dogs and more than 1.035 in cats. The animal's hydration status, serum urea nitrogen and creatinine concentrations, and current medications must be known in order to interpret random urine specific gravity values. For example, a normally hydrated dog may have a urine specific gravity in the isosthenuric range and a cat receiving furosemide may be somewhat dehydrated and still have minimally concentrated urine; however, normal dogs and cats should produce hypersthenuric urine in response to clinically detectable dehydration.

It is unusual for dogs and cats with PD and/or PU to have a urine specific gravity consistently in the hypersthenuric range; this finding warrants the measurement of water consumption to confirm if the patient actually has either condition. Animals with primary polydipsia or with CDI usually have urine specific gravities in the hyposthenuric range, whereas animals with nephrogenic diabetes insipidus are most likely to be isosthenuric or to have minimally concentrated urine. If the history, physical examination, and minimal diagnostic workup findings are unrewarding, specialized diagnostic tests, including determination of the plasma osmolality, gradual water deprivation testing, and determination of the animal's response to exogenous ADH, may be necessary to arrive at a diagnosis (see Chapter 42 and Fig. 41-9).

# **PROTEINURIA**

Normally, the urine of dogs and cats contains only a small amount of protein because the selective permeability of the glomerular capillary wall restricts the filtration of most plasma proteins on the basis of protein weight and charge.

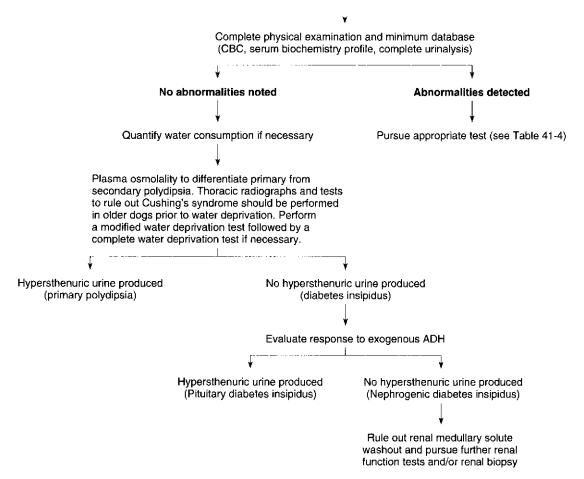

FIG 41-9
Diagnostic approach to dogs and cats with polydipsia and polyuria.

**TABLE 41-4** 

Ancillary Diagnostic Tests that May Be Used to Evaluate Dogs and Cats with Polydipsia and Polyuria

SUSPECTED DISORDER	FURTHER DIAGNOSTIC TESTS	
Primary polydipsia	Plasma osmolality, modified water deprivation, rule out hepatic insufficiency or PSS	
Pituitary diabetes insipidus	Plasma osmolality, modified water deprivation test, response to exogenous antidiuretic hormone	
Nephrogenic diabetes insipidus		
Renal insufficiency or failure	Serum urea nitrogen and creatinine concentrations, creatinine clearance, electrolyte fractional clearance, biopsy	
Hyperadrenocorticism	ACTH-stimulation test, dexamethasone-suppression test, urine cortisol/creatinine ratio	
Hypoadrenocorticism	Serum sodium/potassium ratio, ACTH-stimulation test	
Hepatic insufficiency or PSS	Serum bile acids preprandially and postprandially, abdominal ultrasonography : Doppler, <sup>99</sup> Tc scan (enema), portal angiography, biopsy	
Pyometra	Abdominal radiography or ultrasonography, vaginal cytology	
Hypercalcemia	Serum calcium concentrations (total and ionized), radiography, lymph node cytologi or biopsy, bone marrow cytology, PTH/PTHrp assays	
Hypokalemia	Serum potassium concentration, potassium fractional clearance	
Glucosuria	Obtain concurrent serum glucose concentration	
Hyperthyroidism	Serum total and free thyroxine concentrations, triiodothyronine-suppression test, cardia evaluation, 99Tc scanning	
Renal medullary solute washout	Repeat water deprivation and exogenous ADH testing after gradual water restriction and dietary salt and protein supplementation for 10 to 14 days	

ACTH, Adrenocorticotropic hormone; ADH, antidiuretic hormone; PSS, portosystemic shunt; PTH, parathyroid hormone; PTHrp, parathyroid hormone–related peptide.

**TABLE 41-5** 

Approximate Molecular Weights of Various Plasma Proteins

PLASMA PROTEIN	MOLECULAR WEIGHT (DALTONS)
Insulin Parathyroid hormone Lysozyme Myoglobin Growth hormone Bence Jones proteins (monomer) Amylase Hemoglobin Antithrombin Albumin	6,000 9,000 14,000 17,000 22,000 22,000 50,000 64,500 65,000 69,000
Immunoglobulin G Immunoglobulin A (dimer) Fibrinogen Immunoglobulin M	160,000 300,000 400,000 900,000

Proteins with a molecular weight greater than 60,000 to 65,000 daltons are normally not present in large quantities in normal glomerular filtrate (Table 41-5). The negatively charged glomerular capillary wall further impedes the passage of negatively charged proteins such as albumin. In addition, smaller-molecular-weight proteins, as well as those positively charged proteins that do pass through the glomerular capillary wall, are largely resorbed by the proximal tubular epithelial cells. Such resorbed proteins may be broken down and used by the epithelial cells or returned to the bloodstream, Renal proteinuria most commonly arises because of glomerular capillary wall lesions that allow increased filtration of plasma proteins into the glomerular filtrate. Tubular lesions that result in decreased reabsorption of filtered proteins (primarily albumin) are another source of renal proteinuria. Although glomerular lesions result in greater magnitude of proteinuria compared with tubular lesions, proteinuria associated with both types of lesions tends to be persistent and serves as an important marker of kidney

Proteinuria is routinely detected by semiquantitative methods, including the dipstick colorimetric test and the sulfosalicylic turbidimetric test. The dipstick test is inexpensive and easy to use; amino groups of proteins bind to the indicator incorporated in the filter paper on the dipstick and cause a color change. The color change is graded by comparing it to a standard, but the comparison is subjective. However, automated dipstick analyzers that use reflectance photometry to consistently read the color change and provide a printout of results are available (Idexx VetLab UA Analyzer, IDEXX Laboratories, Westbrook, Maine). The dipstick test is most sensitive to albumin because albumin has more free amino groups than globulins. False-positive results may be obtained if the urine is alkaline, if it has been contaminated

with quaternary ammonium compounds, or if the dipstick is left in contact with the urine long enough to leach out the citrate buffer that is incorporated in the filter paper pad. False-negative results may occur in the setting of Bence Jones proteinuria or dilute or acidic urine. The dipstick test can detect approximately 30 to 1000 mg of protein per deciliter. The dipstick method is not affected by urine turbidity; however, the supernatant from centrifuged urine samples should ideally be used for all physiochemical analyses.

The sulfosalicylic acid test is performed by mixing equal quantities of urine supernate and 3% to 5% sulfosalicylic acid, and subjectively grading the turbidity that results from precipitation of protein on a 0 to 4 scale. This test is also more sensitive to albumin than globulins, but Bence Jones proteinuria can be detected. False-positive results may occur if the urine contains radiographic contrast agents, penicillin, cephalosporins, sulfisoxazole, or the urine preservative thymol. The protein content may be overestimated with the sulfosalicylic acid test if uncentrifuged urine or turbid urine is analyzed. False-negative results may occur if the urine is markedly alkaline or diluted. Because the varying degrees of turbidity are not standardized, results may also vary among laboratories. This test can detect approximately 5 to 5000 mg of protein per deciliter. Further information on such tests is contained in Chapter 42.

Proteinuria detected by these semiquantitative methods should always be interpreted in light of the urine specific gravity and urine sediment. For example, a 2 proteinuria with a 1.010 urine specific gravity is suggestive of a much greater urine protein loss on a 24-hour basis than is a 2 proteinuria with a 1.040 urine specific gravity. Because the urine protein concentration is frequently increased in animals with LUTI or hemorrhage, proteinuria should also be assessed in the context of urine sediment changes indicative of inflammation or hemorrhage (e.g., bacteria and increased numbers of white and red blood cells and epithelial cells in the urine sediment). The evaluation of the animal with proteinuria is further discussed in Chapter 42.

Once persistent proteinuria has been documented, the next step is to identify its source. Proteinuria may be caused by physiologic or pathologic conditions (Table 41-6). Physiologic or benign proteinuria is often transient and abates when the underlying cause is corrected. Strenuous exercise, seizures, fever, exposure to extreme heat or cold, and stress are examples of conditions that may cause physiologic proteinuria. The pathophysiology of physiologic proteinuria is not completely understood; however, relative renal vasoconstriction, ischemia, and congestion are thought to be involved. Decreased physical activity may also affect urine protein excretion in dogs; one study showed that urinary protein loss is higher in dogs confined to cages than in dogs with normal activity. This is different from the postural or orthostatic proteinuria that occurs in people. In the latter condition, mild proteinuria occurs when the person is standing or active but diminishes when the person is recumbent.

Pathologic proteinuria may be caused by urinary or nonurinary abnormalities. Nonurinary disorders associated

with proteinuria often involve the production of small-molecular-weight proteins that are filtered by the glomeruli and that subsequently overwhelm the resorptive capacity of the proximal tubule. Examples of this include the production of immunoglobulin light chains (Bence Jones proteins) by neoplastic plasma cells or lymphocytes and the release of hemoglobin from damaged red blood cells, which then exceeds the binding capacity of haptoglobin (in this case centrifuged urine would be discolored by the pigment). Renal congestion secondary to congestive heart failure can also result in pathologic nonurinary proteinuria, as can genital tract inflammation (e.g., prostatitis or metritis).

Pathologic urinary proteinuria may be renal or nonrenal in origin. Nonrenal proteinuria most frequently occurs in association with LUTI or hemorrhage. Changes seen in the urine sediment usually reflect the underlying cause (e.g., urolithiasis, neoplasia, trauma, bacterial cystitis). On the other hand, renal proteinuria is most often caused by glomerular lesions. Glomerulonephritis and amyloidosis alter the selective permeability of the glomerular capillaries and frequently result in a proteinuria greater than 50 mg/kg/24 h or urine protein: creatinine ratios greater than 2.0 (see Chapter 42). The occurrence of persistent proteinuria with a normal urine sediment or accompanied by hyaline cast formation is strongly suggestive of glomerular disease. Besides glomerular disease, renal proteinuria may be caused by inflammatory or infiltrative disorders of the kidney (e.g., neoplasia, pyelonephritis) or by tubular abnormalities that

result in the decreased resorption of filtered protein (e.g., Fanconi's syndrome and chronic kidney disease).

Prerenal (physiologic and pathologic—nonurinary) and postrenal (pathologic urinary—nonrenal) proteinuria, as well as inflammatory renal proteinuria, can usually be identified on the basis of history and physical examination findings and the urine sediment changes. Renal proteinuria caused by abnormal tubular resorption may be accompanied by normoglycemic glucosuria and an abnormal urinary loss of electrolytes, which can help differentiate tubular from glomerular proteinuria. It is important to identify the source of the proteinuria because the quantification of renal proteinuria can be a helpful prognostic tool, although it is not useful in animals with prerenal or postrenal proteinuria.

# **AZOTEMIA**

Azotemia is defined as increased concentrations of urea and creatinine (and other nonproteinaceous nitrogenous substances) in the blood. The interpretation of serum urea nitrogen and creatinine concentrations as a measure of renal function requires a knowledge of the production and excretion of these substances. Urea is synthesized in the liver from ammonia, which is in turn generated from the catabolism of ingested and endogenous proteins. Urea production is increased in the settings of a high dietary protein intake, upper gastrointestinal tract hemorrhage, and catabolic states that result in the breakdown of body proteins (e.g., fever and corticosteroid administration). Conversely, urea production is decreased in the settings of a low dietary protein intake, use of anabolic steroids, decreased hepatic function, or decreased delivery of ammonia to the liver (e.g., portosystemic shunt). Urea has a small molecular weight (60 daltons) and is a permeate solute that readily diffuses throughout all body fluid compartments; its concentration is similar in intracellular and extracellular fluid and in plasma, serum, and blood. Urea that diffuses into the intestinal lumen is degraded by enteric organisms to ammonia, which is then reabsorbed into the portal circulation and again converted to urea by the liver. Urea is principally excreted by the kidneys; it is freely filtered through the glomeruli and passively resorbed by the renal tubules. The tubular resorption of urea is increased and the net excretion decreased when tubular flow rates and volumes are decreased, as it occurs in patients with dehydration. Conversely, the tubular resorption of urea is decreased and the excretion is increased in the presence of diuresis. Decreased renal blood flow (prerenal causes, such as dehydration or decreased cardiac output) and decreased excretion of urine (postrenal causes, such as urethral obstruction or ruptured bladder), as well as primary renal dysfunction, will result in decreased excretion of urea.

Creatinine is irreversibly formed by the nonenzymatic metabolism of creatine and phosphocreatine in muscle. Creatinine production is relatively constant and proportional to muscle mass; animals with a large muscle mass produce more creatinine each day than do animals with a small muscle mass. For example, serum creatinine concentration in Greyhounds is higher than in dogs of other breeds. Muscle trauma and inflammation do not increase the production of creatinine. In comparison with the urea nitrogen concentration, the creatinine concentration is relatively unaffected by the dietary protein level; however, serum creatinine concentrations can increase after the ingestion of meat and the subsequent increased absorption of creatinine from the gastrointestinal tract. The molecular weight of creatinine is 113 daltons; therefore it diffuses throughout body fluid compartments more slowly than urea does. Some creatinine diffuses into the intestinal lumen, is degraded by enteric bacteria, and is excreted from the body in the feces; however, most creatinine is excreted by the kidneys. Creatinine is freely filtered by the glomeruli and is not significantly resorbed or secreted by the renal tubules. Because the production of creatinine is relatively constant, an increase in the serum creatinine concentration is indicative of decreased renal excretion. It is important to remember, however, that prerenal and postrenal factors influence renal function and, therefore, the excretion of creatinine. Disproportionate increases in blood urea nitrogen (BUN) relative to creatinine can be caused by high-protein diets, upper gastrointestinal hemorrhage, and increased tubular reabsorption of urea nitrogen associated with prerenal azotemia. Conversely, a disproportionately low BUN can be observed with decreased liver function, portosystemic shunts, low-protein diets, and prolonged diuresis.

Rule outs for azotemia include prerenal, renal, and postrenal causes. Any condition that causes a decrease in renal blood flow may result in prerenal azotemia, and this includes hypovolemia (e.g., dehydration, hypoadrenocorticism), hypotension (e.g., anesthesia, cardiomyopathy), and aortic or renal arterial thrombus formation. Initially, the kidneys are structurally and functionally normal in dogs and cats with prerenal azotemia, and they respond to the decreased renal blood flow by conserving water and sodium. Hypersthenuric urine (i.e., specific gravity greater than 1.030 in dogs and greater than 1.035 in cats) with a relatively low concentration of sodium and a high concentration of creatinine is produced (Table 41-7). Elimination of the underlying disorder (e.g., fluid therapy to correct hypovolemia) results in rapid resolution of the azotemia unless the underlying disorder has persisted long enough or is severe enough to have caused renal parenchymal damage.

Postrenal azotemia is usually caused by an obstruction to urine outflow or a rupture of the urine outflow tract. Similar to prerenal azotemia, in postrenal azotemia the kidneys are initially normal; however, the urine specific gravity varies depending on the animal's hydration status. In patients with urethral obstruction, catheterization is difficult and dysuria and stranguria are common clinical signs. Rupture of the urinary tract that results in azotemia usually involves the bladder or urethra, is more common in male than female animals, and frequently results in abdominal effusion or subcutaneous fluid accumulation. Fluid obtained by abdominocentesis is usually sterile and contains a higher concentration of creatinine than the serum does. Even though creatinine is a small molecule and equilibrates rapidly, the concentration of creatinine in the abdominal fluid is higher than that of serum if the kidneys are producing urine that is draining into the abdomen. Positive contrast-enhanced urethrography or cystography is the best way to confirm a rupture of the urethra or bladder.

Renal azotemia occurs as a result of nephron loss or damage. A diagnosis of renal azotemia is confirmed if the azotemia is persistently associated with isosthenuria or minimally concentrated urine (see Table 41-7). Inasmuch as urine is usually stored in the bladder for several hours, it is important not to evaluate the specific gravity of urine produced before the onset of the azotemia. For example, prerenal azotemia may occur in response to acute, severe dehydration; however, the animal may appear to have renal azotemia if the hypersthenuric urine being produced in response to the dehydration is diluted by a larger volume of previously formed, less concentrated urine. The differentiation of prerenal from renal azotemia can be a diagnostic challenge in some animals. Prerenal dehydration causing azotemia and accompanied by a decreased urineconcentrating ability can be confused with renal azotemia. Examples of conditions that can cause this syndrome include furosemide treatment, which causes dehydration, and hypercalcemia, which compromises the urine-concentrating ability and results in dehydration secondary to vomiting. Although fluid therapy is often implemented initially in animals with either prerenal or renal azotemia to manage the dehydration, the prognosis is quite different. Frequently, the response to fluid therapy is the best way to differentiate prerenal from renal azotemia; renal azotemia does not completely resolve in response to fluid therapy alone.

	TABLE	41-7
--	-------	------

Differentiation of Prerenal Azotemia from Acute Renal Failure

Differentiation of Acute from Chronic Renal Failure on the Basis of History, Clinical Signs, and Clinical Pathology Data

#### **Acute Renal Failure**

History of ischemia or toxicant exposure
Normal or increased hematocrit
Enlarged kidneys
Hyperkalemia (with oliguria)
More severe metabolic acidosis
Active urine sediment
Good body condition
Relatively severe clinical signs for level of dysfunction

### Chronic Renal Failure

History of renal disease or polydipsia-polyuria
Nonregenerative anemia
Small, irregular kidneys
Normal or hypokalemia
Normal or mild metabolic acidosis
Inactive urine sediment
Weight loss
Relatively mild clinical signs for level of dysfunction

Renal failure is a state of decreased renal function in which azotemia and the inability to produce hypersthenuric urine persist concurrently. The treatment and prognosis vary for animals with acute renal failure and chronic kidney disease; therefore it is important to distinguish between these two entities. Acute renal failure (ARF) develops within hours or days. Unique clinical signs and clinicopathologic findings often associated with ARF include enlarged or swollen kidneys, hemoconcentration, good body condition, an active urine sediment, relatively severe hyperkalemia and metabolic acidosis, and relatively severe clinical signs for the degree of azotemia (Box 41-3). Chronic kidney disease (CKD) develops over a period of weeks, months, or years, and the clinical signs are often relatively mild for the magnitude of azotemia. Unique signs of CKD often include a history of weight loss and PD/PU, poor body condition, nonregenerative anemia, small and irregular kidneys, and osseous fibrodystrophy caused by secondary renal hyperparathyroidism (see Box 41-3).

#### RENOMEGALY

Renal enlargement is usually detected by physical examination or by abdominal imaging. A quick rule of thumb is that the kidney length on abdominal radiographs should be approximately equivalent to 2.5 to 3 times the length of the second lumbar vertebra in cats and 2.5 to 3.5 times the length of the second lumbar vertebra in dogs. Enlarged kidneys with a normal shape can be caused by edema, acute inflammation, diffusely infiltrating neoplastic disease, unilateral compensatory hypertrophy, trauma (intracapsular hemorrhage), perirenal cysts, or hydronephrosis. Enlarged, abnormally shaped kidneys may be caused by renal neoplasia, cysts, abscesses, hydronephrosis, or hematomas. Ultrasonography, intravenous urography, and advanced imaging (CT scan or magnetic resonance imaging) can be used to further define kidney shape and reveal internal details. Ultrasonography is particularly useful for evaluating enlarged kidneys associated with fluid accumulation (e.g., hydronephrosis, abscesses, and perirenal and parenchymal cysts) and can also be used to guide fine-needle aspiration or needle biopsy of the affected kidney. Kidney biopsy is often necessary to confirm the cause of the renomegaly; however, biopsy is contraindicated if only one kidney is present or if a bleeding disorder, hydronephrosis, a cyst, or an abscess is suspected.

#### RENAL EXCRETORY FUNCTION

#### **GLOMERULAR FILTRATION RATE**

Blood urea nitrogen (BUN) and creatinine concentrations provide a crude index of the glomerular filtration rate (GFR). However, inasmuch as the creatinine concentration is influenced by fewer extrarenal variables and creatinine is not resorbed by the renal tubules, the serum creatinine concentration is a better index of GFR than is the BUN. Nevertheless, azotemia resulting from impaired renal function is not detectable until approximately three fourths of the nephrons in both kidneys are nonfunctional. This percentage may be even higher in dogs and cats with chronic progressive renal disease because the remaining viable nephrons often undergo compensatory hypertrophy. Therefore renal clearance and measurement of GFR can provide more accurate information about renal excretory function than the serum creatinine and BUN concentrations, especially early in renal disease, before three fourths of the nephrons have been destroyed.

Renal clearance is the rate at which a substance is completely cleared from a certain volume of plasma. Substances used to measure renal clearance must be freely filtered by the glomerulus (not protein-bound) and not affected by tubular resorption or secretion or by metabolism elsewhere in the body. In addition, the substance used must not alter renal function. The renal clearance of inulin is the gold standard method of determining GFR, but it is difficult to measure the inulin concentration in plasma and urine. On the other hand, it is relatively easy to determine the renal clearance of creatinine and therefore more practical. The renal clearance of creatinine can be calculated by multiplying the concentration of creatinine in urine by the rate of urine production and then dividing the product by the serum concentration of creatinine, as follows:

Volume of plasma cleared  $(ml/min) = GFR (ml/min) = (Urine_{Cr}[mg/dl] \times Urine volume [ml/min)] = Serum_{Cr} (mg/dl)$ 

For example, if the urine creatinine concentration is 60 mg/dl, urine production is 3 ml/min, and the serum creatinine concentration is 1.8 mg/dl, 100 ml of plasma is cleared of creatinine per minute. This value is divided by the animal's body weight in kilograms and expressed in milliliters per minute per kilogram. Note that prerenal and postrenal factors, as well as renal parenchymal lesions, influence plasma clearance.

The GFR can be calculated using the clearance of either endogenous or exogenous creatinine. Endogenous creatinine clearance, however, requires urine collection for a lengthy period (i.e., 24 hours) to minimize errors in the collection, thus necessitating the use of indwelling catheters, repeated urinary catheterization, or the use of metabolism cages for urine collection. Endogenous creatinine clearance can be used in the clinical setting to evaluate renal excretory function if renal dysfunction is suspected, but the serum urea nitrogen and creatinine concentrations are within normal ranges. In early renal disease, a relatively large decline in GFR results in small changes in serum creatinine concentrations within the normal range. Less commonly, endogenous creatinine clearance can be used to better quantify renal excretory function in animals with azotemia because in advanced renal disease relatively large changes in serum creatinine concentrations are accompanied by much smaller decreases in GFR. A serum sample obtained approximately midway through the urine collection period and a well-mixed aliquot

BOX 42-1

Calculation of Endogenous Creatinine Clearance, 24-Hour Urine Protein Excretion, and Urine Protein/ Creatinine Ratio

#### Data

Body weight = 20 kg 24-hour urine volume = 400 ml (4.0 dl) Urine protein concentration = 650 mg/dl Urine creatinine concentration = 110 mg/dl Serum creatinine concentration = 1.9 mg/dl Time—24 hours = 1440 minutes

#### Calculations

Endogenous creatinine clearance =  $\frac{\{Urine_{Cr}\} \times \{Urine \ volume\}}{\{Serum_{Cr}\} \times \{Time\} \times \{Body \ weight\}}, \text{ or } \\ \frac{(110 \ mg/dl) \times (400 \ ml)}{\{1.9 \ mg/dl\} \times (1440 \ min) \times (20 \ kg)} = \\ 0.8 \ ml/min/kg$ 

24-hour urine protein excretion =

$$\frac{(650 \text{ mg/dl}) \times (4.0 \text{ dl})}{(20 \text{ kg})} = 130 \text{ mg/kg}$$

#### Data

Urine protein from random urine sample = 750 mg/dl Urine creatinine from random urine sample = 120 mg/dl

#### Calculation

Urine protein/creatinine ratio = (750 mg/dl)/(120 mg/dl) = 6.25 6.25 × 20 (linear regression conversion factor) = 125 mg of urine protein/kg/24 hours

from the 24-hour urine sample are used to measure creatinine concentrations. The volume of urine collected is divided by 1440, the number of minutes in 24 hours (Box 42-1). One drawback to this method, however, is the fact that noncreatinine chromogens present in the serum falsely increase serum creatinine concentrations if the standard alkaline picrate method of analysis is used, especially when serum creatinine concentrations are within the normal range or only mildly increased. In fact, noncreatinine chromogens can account for as much as 50% of the total amount of chromagens in animals with serum creatinine concentrations within normal ranges. Because noncreatinine chromogens are not excreted in the urine, the calculated endogenous creatinine clearance can be falsely decreased. Despite this problem, endogenous creatinine clearance has been shown to closely approximate inulin clearance in dogs and cats. Normal values for endogenous creatinine clearance in the dog and cat are 2.8 to 3.7 and 2 to 3 ml/min/kg, respectively.

The clearance of exogenous creatinine can be determined over a relatively short period, and because the serum creatinine concentration is considerably increased, the effect of

noncreatinine chromogens is largely negated. Measurement of exogenous creatinine clearance is most appropriate in nonazotemic animals. Initially, a constant intravenous infusion of creatinine was used in the test; however, research has shown that a single subcutaneous injection of 100 mg of creatinine per kilogram of body weight (Sigma Chemicals, St. Louis, Missouri) can be used instead. Urine is collected for 20 minutes, starting 40 minutes after the injection, and serum samples are obtained at the start and end of the collection period (the average of the two serum creatinine concentrations is used to calculate creatinine clearance). Because of the short collection period, it is important to rinse the bladder with a sterile saline solution at the start and end of the collection. To increase the accuracy of this technique, two 20-minute clearances can be calculated and averaged. Normal exogenous creatinine clearance values are 3.5 to 4.5 ml/min/ kg in dogs and 2.4 to 3.3 ml/min/kg in cats.

Plasma clearance of iohexol, an iodinated radiographic contrast agent, has been shown to reliably estimate GFR in dogs and cats. Because calculation of iohexol clearance does not require urine collection, the procedure is less labor intensive and invasive compared with creatinine clearance. Iohexol plasma clearance can be performed in dogs and cats that are well hydrated and fasted for 12 hours before the study. Iohexol (e.g., Omnipaque 240 mg I/ml, available from GE Healthcare, Inc., Princeton, NJ) is administered intravenously at the dosage of 300 mg iodine/kg body weight. Blood samples are collected at 2, 3, and 4 hours after the intravenous (IV) injection. Serum from each blood sample is harvested (approximated 1.5 ml of serum is needed per sample) and then shipped either chilled or frozen to the university teaching hospital or specialized reference laboratory (e.g., Diagnostic Center for Population and Animal Health, Toxicology Section, Michigan State University).

Renal scintigraphy using technetium 99m-labeled diethylenetriaminepentaacetic acid also allows the GFR to be evaluated and is available at several universities and major referral centers. This is a quick, noninvasive method that does not require urinary catheterization and has the advantage of being able to quantitatively evaluate individual kidney function. Disadvantages of this procedure include its limited availability, exposure of the animal to radioisotopes, the need for radioisotope disposal, and poorer correlation with inulin clearance when compared with plasma clearance techniques such as that used with iohexol.

#### FRACTIONAL CLEARANCE

The clearance of various solutes in the urine may be compared with the clearance of creatinine in the urine to assess the degree of tubular resorption or secretion. Because the renal clearance of creatinine is relatively constant over time, expressing the renal clearance of a solute as a percentage of the clearance of creatinine gauges the body's attempt to conserve or excrete the solute. The fractional clearance (FC) of a solute is the quotient of the urine: serum solute ratio divided by the urine: serum creatinine ratio ([Urine<sub>S</sub>: Serum<sub>S</sub>]/[Urine<sub>Gr</sub>: Serum<sub>Gr</sub>]). A timed urine collection is not

necessary to determine the FC of a solute. Some solutes, including glucose and amino acids, are normally highly conserved, whereas electrolytes such as sodium, chloride, potassium, calcium, and phosphorus are variably conserved. In normal dogs and cats the FCs of sodium, chloride, and calcium are less than 1%; however, the FCs of potassium and phosphorus are more variable and may be as high as 20% and 39%, respectively. Examples of situations in which a knowledge of the FC of electrolytes may be helpful include (1) the diagnosis of primary hyperparathyroidism, in which the FC of phosphorus is increased; (2) the diagnosis of tubular dysfunction, such as Fanconi's syndrome, in which the FCs of all electrolytes are increased; and (3) the differentiation of prerenal azotemia, in which the FC of sodium is decreased, from acute renal failure, in which the FC of sodium is increased (>2%; see Table 41-3). In many cases, however, the correlation between spot urine sample and 24hour urine sample FC is poor. In addition, the amount of dietary intake of the electrolyte in question can influence results, and there tends to be large intrapatient and interpatient variation in results. Moreover, the FC may also be breed dependent; for example, FC of most electrolytes is significantly different in Greyhounds than in other dog breeds. For these reasons, the clinical usefulness of FC of electrolytes is limited.

# **QUANTIFICATION OF PROTEINURIA**

If the results of the dipstick or sulfosalicylic acid test for proteinuria (see Chapter 41) indicate the presence of persistent proteinuria and the urine sediment examination findings are normal (i.e., renal proteinuria is suspected), urine protein excretion should be quantified. This helps in evaluating the severity of renal lesions and assessing the response to treatment or the progression of disease. The trichloroacetic acid-N-Ponceau S, Coomassie brilliant blue, or benzethonium chloride tests are the most common methods used to quantify urine protein and are available at referral centers and reference laboratories.

The urine protein: creatinine ratio in canine and feline urine samples has been shown to accurately reflect the quantity of protein excreted in the urine over a 24-hour period. Both urine creatinine and urine protein concentrations are affected by urine volume and urine concentration, but the ratio of the urine protein to urine creatinine is not. This allows quantitation of proteinuria without the need to collect a timed urine sample, and therefore the test has greatly facilitated the diagnosis of kidney disease in small animals. A urine protein; creatinine ratio of less than 0.4 and less than 0.5 is considered normal in cats and dogs, respectively. A complete urinalysis should always be performed before or along with determination of the urine protein: creatinine ratio because hematuria or pyuria may indicate the presence of nonglomerular proteinuria. If there is evidence of inflammation (e.g., pyuria, bacteriuria), the protein concentration should be measured again after successful treatment of the inflammatory disorder. The urine protein: creatinine ratio cannot be used to differentiate between renal proteinuria and proteinuria associated with lower urinary tract inflammation or hemorrhage. The urine protein:creatinine ratio provides a noninvasive way to follow progression of disease or response to treatment. The variation in urine protein: creatinine observed in dogs with stable proteinuria suggests that the ratio should differ by 80%, especially with lower range proteinuria, in order to conclude that a significant change has occurred. In cats the urine protein: creatinine variation within the reference range suggests that the ratio should differ by 90% to conclude that a significant increase or decrease in proteinuria has occurred. Typically, quantitative measurement of urine protein and creatinine (mg/dl) is performed at reference laboratories and teaching hospitals; however, in-house quantitative urine protein: creatinine measurement has recently become available (Idexx VetTest Chemistry Analyzer, IDEXX Laboratories, Westbrook, Maine), and results appear to correlate well with standard quantitative methodologies.

Antigen capture enzyme-linked immunosorbent assays (ELISA) used to detect low levels of albumin in canine and feline urine (microalbuminuria [MA]) are commercially available (E.R.D.-Screen, Heska Corp., Fort Collins, Colorado). MA is usually defined as a urine albumin concentration between 1.0 and 30 mg/dl. These are concentrations too low to be routinely detected by standard dipstick screening tests. It is interesting to note that the presence of MA has been shown to be an accurate predictor of subsequent renal disease in human beings with both systemic hypertension and diabetes mellitus, and it has also been observed in human beings with systemic diseases that are associated with glomerulopathy. Studies in dogs have shown the prevalence of MA in apparently healthy dogs and Soft Coated Wheaten Terriers genetically predisposed to developing glomerular disease to be 19% and 76%, respectively (Jensen et al., 2001; Vaden et al., 2001). In additional studies, development of MA preceded the development of overt albuminuria in dogs with experimentally induced heartworm disease (Grauer et al., 2002) and in dogs with X-linked hereditary nephropathy (Lees et al., 2002). MA testing should be used when conventional screening tests for proteinuria are negative and increased sensitivity is desired (e.g., screening for early kidney disease in young animals that may have heritable kidney disease or screening for acquired chronic kidney disease in older animals). A positive MA test of suspected renal origin should be pursued with a three-step paradigm of (1) monitoring, (2) investigating, and (3) intervening. The initial step of monitoring involves determining if the albuminuria is persistent or transient. It is important to note that the sensitivity of MA assays makes it likely that some positive results will be caused by benign or physiologic proteinuria. In these cases, follow-up assays should be negative, confirming that the MA was transient. Transient MA is likely to be of little or no consequence. On the other hand, persistent proteinuria/albuminuria of renal origin indicates the presence of kidney disease. Persistent proteinuria/albuminuria can be defined as positive test results on  $\geq 2$  occasions,  $\geq 2$ weeks apart. Because persistent proteinuria/albuminuria can be constant or increase or decrease in magnitude over time, monitoring should use quantitative methods to determine disease trends and/or response to treatment. Quantitative albuminuria assays or the urine protein/creatinine ratio are used to document changes in the magnitude of the albuminuria once its persistence has been confirmed. Changes in the magnitude of proteinuria should always be interpreted in light of the patient's serum creatinine concentration because albuminuria may decrease in association with progressive renal disease as the number of functional nephrons decrease. Decreasing albuminuria in the face of a stable serum creatinine concentration suggests improvement in renal function, whereas decreasing albuminuria in the face of an increasing serum creatinine suggests disease progression.

Once persistent proteinuria has been documented by monitoring, the appropriate response depends on the magnitude of the proteinuria and the health status of the patient (e.g., the presence or absence of azotemia and/or hypertension). The second step of investigation refers to performing new or additional tests to diagnose an underlying/concurrent infectious, inflammatory, or neoplastic disease process or to more completely define the patient's renal disease. Examples of such further investigation may include a complete minimum database, urine culture, measurement of blood pressure, serology for immune-mediated or infectious diseases, radiographs/ultrasound, and renal biopsy.

In cases of persistent proteinuria, where an underlying disorder cannot be identified or treated, the need for treatment of the proteinuria depends on its magnitude and the presence or absence of azotemia. In the absence of azotemia, proteinuria resulting in urine protein: creatinine ratios >1.0 to 3.0 should be treated, whereas continued monitoring and patient investigation should be the primary focus in cases with lesser-magnitude proteinuria. Treatment recommendations in these cases usually include decreased dietary protein intake (early renal failure diets), n-3 fatty acid supplementation (early renal failure diets), low-dose aspirin (0.5 mg/kg q24h administered orally), and angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril, benazepril; 0.5 to 1.0 mg/kg q24h administered orally), although it is difficult to separate the effects of individual treatments when they are used in combination. Treatment for persistent proteinuria in azotemic dogs and cats should be initiated when the urine protein:creatinine ratio is ≥0.5 and 0.4, respectively. Treatment recommendations in this case usually include ACE inhibition and renal failure diets.

Urine and serum protein electrophoresis may help in identifying the source of the proteinuria and in establishing a prognosis. For example, proteinuria associated with hemorrhage into the urinary tract has an electrophoretic pattern very similar to that of serum. Early glomerular damage usually results principally in albuminuria; however, as the glomerular disease progresses, an increasing amount of globulin may be lost as well. Marked hypoalbuminemia and increased concentrations of larger-molecular-weight pro-

teins in the serum indicate the presence of severe glomerular proteinuria and the nephrotic syndrome.

# PLASMA AND URINE OSMOLALITY, WATER DEPRIVATION TEST, AND RESPONSE TO EXOGENOUS ANTIDIURETIC HORMONE

Measurement of plasma osmolality may aid in the determination of the primary component of the polydipsia/polyuria (PD/PU) syndrome. Normal plasma osmolality in dogs and cats is 280 to 310 mOsm/kg. Plasma osmolality in animals with primary PD is usually low (275 to 285 mOsm/kg), reflecting the dilutional effect of excessive water consumption. In contrast, animals with a primary PU often have high plasma osmolalities (305 to 315 mOsm/kg) because of their inability to concentrate urine and the resultant dehydration (see Fig. 41-9). However, there can also be considerable overlap in randomly obtained plasma osmolalities between animals with primary polydipsic disorders and those with primary polyuric disorders.

Determination of a urine: plasma osmolality ratio allows a more precise determination of urine concentration than does urine specific gravity alone because specific gravity measures the density of urine rather than the number of particles in solution. For example, moderate-to-marked glucosuria or proteinuria increases urine specific gravity more than the urine osmolality. In response to dehydration, normal dogs and cats should be able to form urine that is five to six times more concentrated than plasma. Plasma and urine osmolality may be determined using either a vapor pressure or freezing point depression osmometer, and measurement is available at a reasonable cost at most veterinary teaching hospitals and reference laboratories.

Water deprivation causes dehydration and plasma hyperosmolality and allows the neurohypophyseal-renal axis to be evaluated. Water deprivation tests are used to differentiate diabetes insipidus from primary PD and should be performed only after other causes of PU and PD have been ruled out on the basis of the findings from physical examination and a minimum database. It should be noted that water deprivation tests are potentially dangerous. They should therefore be performed only under close observation and after water intake has been gradually reduced (see later discussion) because failure to produce concentrated urine (i.e., diabetes insipidus) may result in severe dehydration and potential ischemic renal injury. Increases in plasma osmolality of 1% to 2% above normal levels stimulate the release of antidiuretic hormone (ADH), and normal kidneys should respond to this ADH by producing hypersthenuric urine. The water deprivation test is complete when the animal loses 5% of its body weight as a result of dehydration, becomes azotemic, becomes hyperosmolemic (plasma osmolality ≥320 mOsm/kg), or produces hypersthenuric urine (specific gravity ≥1.030 in dogs or ≥1.035 in cats). It is important to obtain accurate baseline values and ensure that the bladder is emptied each time the urine specific gravity or osmolality is measured so that urine produced between evaluations is not diluted by previously formed urine. Plasma osmolality constitutes a good measure of hydration status during water deprivation, and, in fact, a water deprivation test may not be necessary if it is measured at baseline. The finding of a baseline plasma osmolality of 320 mOsm/kg or greater in a clinically nondehydrated dog or cat with hyposthenuria or isosthenuria indicates a failure of the neurohypophysealrenal axis. Similarly, a water deprivation test should not be performed in an animal that is clinically dehydrated or azotemic and that has hyposthenuria, isosthenuria, or minimally concentrated urine because these conditions already demonstrate a failure of the neurohypophyseal-renal axis. The time it takes to reach the end-point of a water deprivation test is variable; small dogs and cats may dehydrate within several hours, whereas significant dehydration may not occur in large dogs for 36 to 48 hours. Animals that fail to produce hypersthenuric urine in response to water deprivation have either pituitary or nephrogenic diabetes insipidus.

A pharmacologic dose of ADH may be administered to differentiate pituitary diabetes insipidus (lack of ADH) from nephrogenic diabetes insipidus (no response to ADH). Aqueous ADH (3 to 5 U given intramuscularly) is commonly used for diagnostic testing, although synthetic desmopressin acetate nasal spray, given as drops in the conjunctival sac, or an injectable preparation of desmopressin acetate, given subcutaneously (3 to 5 U), may also be used. The ADH should be administered immediately at the end-point of the water deprivation test, before water is made available, in animals that do not respond to water deprivation. It is important that the bladder be empty immediately before the administration of ADH so that the urine produced in response to ADH is not diluted by previously formed urine. Animals with central diabetes insipidus (CDI) usually respond by producing urine that is hypersthenuric or at least ≥1.025 within 1 to 2 hours. The absence of an increase in urine specific gravity in response to both water deprivation and exogenous ADH administration indicates the presence of nephrogenic diabetes insipidus (NDI).

Renal medullary hypertonicity may be lost after prolonged PU (primary or secondary). Therefore medullary washout may develop in animals with primary PD or CDI, making them appear to have NDI. Water intake may be gradually reduced over 10 to 14 days to correct renal medullary washout before the water deprivation test is performed. In addition to gradually limiting the dog's or cat's water intake (10% reduction every other day until the animal is drinking 80 to 90 ml/kg/day), a high-protein diet that is lightly salted (unless the patient is hypertensive) should be fed to the animal to facilitate reestablishment of normal medullary tonicity. Water restriction should be discontinued if the animal becomes overly aggressive in its desire for water or becomes lethargic or weak. The response to water deprivation and, if necessary, the response to exogenous ADH should be evaluated after 10 to 14 days of this gradual water deprivation. The lack of a response to water deprivation and exogenous ADH administration after gradual water reduction suggests that NDI unrelated to medullary washout is the cause of the PD/PU.

# **BLADDER AND URETHRAL FUNCTION**

Several specialized diagnostic tests, including urethral pressure profilometry, cystometry, and uroflowmetry, may help categorize bladder and urethral function in dogs and cats with disorders of micturition. These tests are available at many referral centers. The urethral pressure profile (UPP) assesses the perfusion pressure or minimal distention pressure within the bladder and urethra during the storage phase of micturition. The functional urethral length (the length of the urethra that has a pressure greater than the intravesical pressure) and the functional urethral closure pressure (the greatest urethral pressure minus the intravesical pressure) can be determined on the basis of a UPP. Electromyography may be combined with a UPP to define the portion of urethral resistance contributed to by periurethral striated muscle (external sphincter). The UPP can be used to assess urethral sphincter tone in animals with suspected urethral sphincter incompetence or functional urethral obstruction and urethral spasm. In addition, the UPP can be used to evaluate sphincter response to treatment with α-adrenergic drugs or estrogens. Finally, the UPP should be determined preoperatively to evaluate urethral sphincter function in dogs and cats with ectopic ureters or vaginal strictures because of the increased incidence of sphincter incompetence in animals with these congenital anomalies. A cystometrogram records changes in intravesical pressure during bladder filling and detrusor contraction. It evaluates the detrusor reflex, maximal detrusor contraction pressure, and bladder capacity and compliance in animals with suspected detrusor atony, instability, and decreased capacity or compliance. Uroflowmetry measures urine flow during the voiding phase of micturition and defines the relationship between urine flow and detrusor contraction. The presence of normal, increased, or decreased urethral resistance can be established with uroflowmetry.

# BACTERIAL ANTIBIOTIC SENSITIVITY TESTING

The majority of simple, uncomplicated urinary tract infections in female dogs can be effectively treated with an antibiotic chosen on the basis of urine sediment Gram staining or culture and sensitivity based on the disk-diffusion/Kirby Bauer method. If disk-diffusion sensitivity testing shows that the organism is highly resistant to antibiotics (e.g., susceptible only to aminoglycosides), minimum inhibitory concentration (MIC) sensitivity testing can be helpful because of differences in the serum and urine concentrations of antibiotics. In these cases, in vivo sensitivity may exist even though

TABLE 42-1

Urine Concentration of Selected Antimicrobial Agents in Healthy Dogs with Normal Renal Function

ANTIBIOTIC	DOSAGE*	ROUTE	URINE CONCENTRATION ( $\mu$ g/mL; MEAN $\pm$ STANDARD DEVIATION)
n · · · · · · · · · · · ·	40,000 11/1 01	PO.	294 ± 211
Penicillin G	40,000 U/kg q8h	PO	
Ampicillin	25 mg/kg q8h	PO	309 ± 55
Amoxicillin	11 mg/kg q8h	PO	202 ± 93
Tetracycline	20 mg/kg q8h	PO	138 ± 65
Chloramphenicol	33 mg/kg q8h	PO	124 + 40
Sulfisoxazole	22 mg/kg q8h	PO	1466 ± 832
Cephalexin	30 mg/kg q12h	PO	805 ± 421
Trimethoprim/sulfa	15 mg/kg q12h	PO	55 ± 19
Enrofloxacin	2.5 mg/kg q12h	PO	43 ± 12

<sup>\*</sup> Dosages are the same for cats, except that the dosage or chloramphenicol in cats is 20 mg/kg q8h for 1 week. PO, Orally.

disk-diffusion sensitivity testing has shown in vitro resistance. For example, the MICs of penicillin for staphylococcal organisms, including penicillinase-producing strains, are approximately  $10~\mu g/ml$ . The average urine concentration of ampicillin, when given in standard doses orally, exceeds  $300~\mu$  g/ml, whereas the expected serum concentration is only 1 to  $2~\mu$  g/ml. The general rule of thumb in interpreting MICs is that if the MIC is 25% or less of the expected mean urine concentration (Table 42-1), the organism should be susceptible. However, MIC sensitivity should not be used in animals with pyelonephritis, prostatitis, or bladder infections with a thickened bladder wall because drug concentrations in these tissues will be closer to serum concentrations than to urine concentrations.

# **DIAGNOSTIC IMAGING**

It is relatively difficult to visualize the entire outline of both kidneys on plain abdominal radiographs; the right kidney is usually more difficult to visualize than the left because of its close association with the caudate lobe of the liver. It is even more difficult to visualize the kidneys in thin or emaciated animals because the contrast provided by abdominal fat is lacking. Plain abdominal radiographs are valuable to evaluate kidney number, location, size, shape, and radiographic density (Table 42-2). Kidney size is best estimated by comparing kidney length with the length of adjacent lumbar vertebrae; the kidneys should be approximately equivalent to 2.5 to 3 times the length of the second lumbar vertebra in cats and 2.5 to 3.5 times the length of the second lumbar vertebra in dogs. Canine kidneys are generally bean shaped, whereas feline kidneys are more spherical. The right kidney is approximately one-half length cranial to the left kidney in both cats and dogs, and the kidneys of cats are more movable than those of dogs. Kidneys have a soft tissue or water density throughout and are more dense than the perirenal fat. Any radiopacity within the kidney is abnormal (Fig. 42-1).

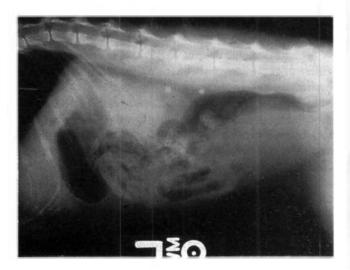

FIG 42-1
Plain film radiographic appearance of bilateral renal calculi in a cat. (Courtesy Dr. Phillip Steyn, Colorado State University, Fort Collins, Colo.)

Ultrasonography is used to evaluate renal tissue architecture if kidney abnormalities have been detected by physical examination (e.g., abnormal kidney size or shape), clinicopathologic findings (e.g., azotemia or proteinuria), or survey radiographs (e.g., abnormal kidney size, shape, or opacity or nonvisualization of a kidney). Ultrasonography can provide information about the tissue architecture of the kidneys. Normally, the renal cortex is hypoechoic compared with the spleen, and the renal medulla is hypoechoic compared with the cortex (Fig. 42-2). The renal pelvis and diverticula are relatively hyperechoic. Relatively hypoechoic renal cortices can be observed in patients with acute tubular necrosis, polycystic kidney disease, abscesses, or renal edema associated with acute renal failure. Conversely, relatively hyperechoic renal cortices are associated with chronic kidney disease (CKD), nephrocalcinosis, amyloidosis, feline infectious peritonitis, and calcium oxalate nephrosis secondary to ethylene glycol ingestion. Glomerular and tubulointerstitial disease

can show a normal or hyperechoic echotexture depending on chronicity. Renal lymphoma can make the renal cortices appear hypoechoic or hyperechoic (Fig. 42-3). Hydrone-phrosis and hydroureters are easily and noninvasively diagnosed on the basis of ultrasonographic findings (Fig. 42-4). Resistance to renal blood flow (resistive index), which can be calculated with the use of color flow Doppler imaging, is increased in association with several renal diseases.

An intravenous urogram (Box 42-2) can also aid in the evaluation of renal structures, specifically the renal vessels, parenchyma, and pelvis, as well as the ureters (Fig. 42-5). Potential indications for IV urography include kidney abnormalities noted on plain radiographs or ultrasonograms, inability to visualize one or both kidneys on plain radiographs or ultrasonograms, and hematuria of suspected renal origin. In addition, IV urography qualitatively assesses individual kidney excretory function; therefore it should be performed before nephrectomy or nephrotomy if other means of assessing GFR are not available. The utility of IV urography diminishes if azotemia exists, and good renal opacification

becomes more difficult as azotemia increases. IV urography should be avoided in dehydrated animals and in those receiving potentially nephrotoxic drugs.

If the ureters are normal, they cannot be visualized on plain radiographs. Normal ureters appear as radiopaque lines that extend from the kidneys to the trigone region of the bladder on IV urograms (see Fig. 42-5, B). The normal ureteral diameter is 1 to 2 mm, and apparent filling defects are frequently caused by peristaltic contractions that propel urine and contrast material to the bladder. Indications for intravenous urography to evaluate the ureters include suspected obstructive uropathy (Fig. 42-6), trauma (rupture or laceration), calculi, ectopic ureters (Fig. 42-7), neoplasia, and ureterocele.

The size, shape, and position of the urinary bladder can usually be evaluated and any radiopacities detected on plain abdominal radiographs and ultrasonograms (Fig. 42-8). However, retrograde contrast-enhanced radiographic studies are easy to perform and are used to visualize the entire bladder and its relationship to other structures in the

# BOX 42-2

#### Technique for Intravenous Urography

1. Patient preparation:

No food for 24 hours, water available, free choice One or more enemas at least 2 hours before radiography

Assess hydration status; do not proceed if animal is dehydrated.

- 2. Evaluate survey radiographs for effectiveness of enemas.
- 3. Use sedation only if necessary.
- 4. Infuse contrast solution intravenously via jugular or cephalic vein as bolus injection.

880 mg/kg iodine; dose can be doubled if renal function is poor.

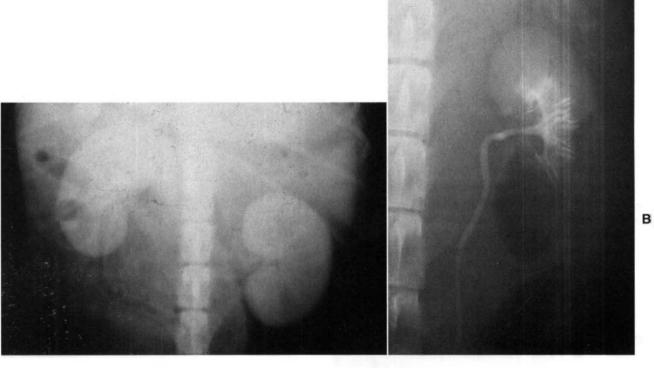

Nonionic iodinated contrast solutions are safest but more expensive.

5. Obtain abdominal radiographs as follows:

Ventrodorsal views at 5 to 20 seconds, 5 minutes, 20 minutes, and 40 minutes after injection

Lateral view at 5 minutes

Oblique views at 3 to 5 minutes to assess ureteral termination in bladder

**FIG 42-5**Radiographic appearance of normal canine kidneys during **(A)** the nephrogram stage of an intravenous pyelogram and **(B)** the pyelogram stage of an intravenous pyelogram.

posterior abdomen. Negative (air or carbon dioxide) or positive (iodinated contrast medium) contrast material may be used for contrast-enhanced cystography (Fig. 42-9); however, double-contrast studies (bladder is filled with a positive-contrast medium that is removed and replaced with air or carbon dioxide) provide the best information about the bladder mucosal surface (Fig. 42-10). Abnormalities that may be identified by contrast-enhanced cystography include mucosal and mural lesions, luminal filling defects, urachal remnants, diverticuli, vesicoureteral reflux, extraluminal masses, radiolucent calculi, and bladder tears.

Ultrasonography can also be used to evaluate the urinary bladder, in most cases without the sedation and urinary catheterization required for contrast-enhanced cystography. It is particularly useful for differentiating intraluminal

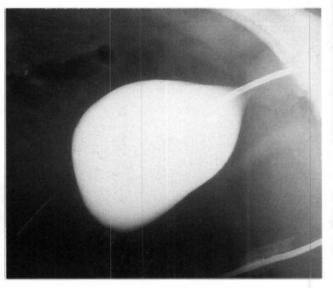

FIG 42-9

masses (e.g., calculi, blood clots, tumors, polyps; Figs. 42-11 and 42-12). The prostate gland and sublumbar lymph nodes are also easily evaluated with ultrasonography. However, it may be less effective than contrast-enhanced cystography in detecting subtle mucosal irregularities, small uroliths, and bladder rupture.

Similar to the ureters, the urethra is not routinely visualized on plain radiographs. Contrast-enhanced urethrography is most frequently performed in male dogs and cats to detect or rule out urethral obstruction or rupture (Figs. 42-13 and 42-14). It may be used to identify the presence and location of mucosal and mural lesions, luminal filling defects, strictures, an extramural compression, and urethral rupture or laceration.

Computed tomography (CT), both plain and with contrast, and magnetic resonance imaging (MRI) are increasingly used for evaluation of urinary tract pathology at teaching hospitals and other referral centers. The three-dimensional anatomical information provided by CT and MRI can be helpful in surgical planning, especially for detection of tumor invasion into adjacent tissues. Intravenous urography with CT is an excellent imaging technique for detection of ectopic ureters, and GFR can be calculated using contrast-enhanced CT images of the kidneys.

#### CYSTOSCOPY

Cystoscopy allows relatively noninvasive visualization and biopsy of the urethral and bladder mucosal surface. In some cases, bladder mucosal lesions can be biopsied or resected and uroliths removed or crushed by means of cystoscopy. Finally, cystoscopy can be used to catheterize the ureters to

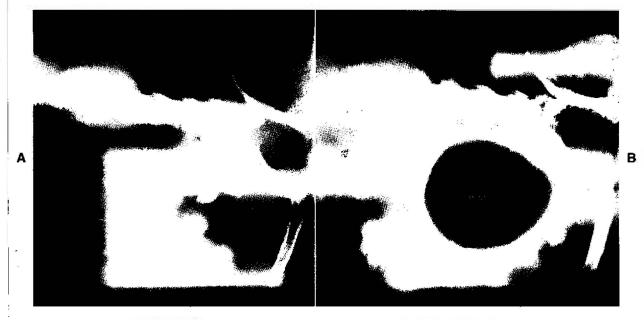

FIG 42-10

obtain urine samples and perform retrograde pyelography. Cystoscopy is used to evaluate patients with lower urinary tract inflammation, to evaluate potential anatomic abnormalities in animals with recurrent urinary tract infections (e.g., urolithiasis, polyps, urachal remnants) and animals with urine retention or incontinence, to evaluate and obtain a biopsy specimen of bladder or urethral masses, and to differentiate unilateral from bilateral renal hematuria.

# **RENAL BIOPSY**

The biopsy and histopathologic evaluation of renal tissue is a valuable diagnostic and prognostic tool. Renal biopsy should be considered if the diagnosis is in question (e.g., immune complex glomerulonephritis versus amyloidosis in dogs with proteinuria), if treatment may be altered on the basis of results (e.g., confirmation and culture of bacterial pyelonephritis), or if the prognosis may be altered on the basis of results (e.g., evidence of reversible tubular lesions in a dog or cat with acute tubular necrosis). A specific diagnosis is required to implement specific treatment in most animals with renal disease, and a biopsy frequently must be performed for a specific diagnosis to be obtained. In addition, the prognosis for animals with renal disease is most accurate if it is based on three variables: the severity of dysfunction, the response to treatment, and the renal histopathologic findings.

Renal biopsy should be considered only after less invasive tests have been done and the blood clotting ability has been assessed. Absolute or relative contraindications to renal biopsy include a solitary kidney, a coagulopathy, severe systemic hypertension, and renal lesions associated with fluid accumulation (e.g., hydronephrosis, renal cysts and abscesses). In addition, renal biopsy should not be attempted by inexperienced clinicians or in animals that are not adequately restrained.

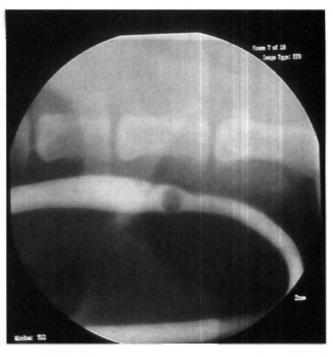

Renal biopsy specimens can be obtained percutaneously using the keyhole technique or under laparoscopic or ultrasonographic guidance. In many cases the best way to obtain a specimen is at laparotomy, when both kidneys can be visualized, because postbiopsy hemorrhage can then be accurately assessed and treated and an adequate biopsy specimen ensured. The cortical region of the kidney should be biopsied to obtain an adequate number of glomeruli in the specimen and to avoid renal nerves and major vessels in the medullary region. Most animals will have microscopic hematuria for 1 to 3 days after the biopsy procedure, and overt hematuria is not uncommon. In a retrospective study by Vaden (2007) of renal biopsies in 283 dogs and 65 cats, complications were reported in 13.4% and 18.5% of dogs and cats, respectively. The most common complication was severe hemorrhage; hydronephrosis and death were uncommon. Dogs that developed complications after renal biopsy were more likely to have been 4 to <7 years of age and >9 years, to weigh ≤5 kg, and to have serum creatinine concentrations >5 mg/dL. The majority of biopsies from both dogs (87.6%) and cats (86.2%) were considered to be of satisfactory quality. Biopsies from dogs were more likely to be of high quality if they were obtained when the patient was under general anesthesia and more likely to contain only renal cortex if they were obtained by surgery. It was concluded that renal biopsy is a relatively safe procedure, with a low frequency of severe complications.

To prevent artifactual changes, care must be exercised when handling and fixing renal tissue. It is important to consult the histopathology laboratory before performing the biopsy to ensure that appropriate fixatives are used. When possible, immunofluorescent or immunohistochemical techniques and electron microscopy should be used to maximize the information gained from the biopsy specimen. Communication with the laboratory pathologist before biopsy will help determine which fixatives should be used and will maximize the utility of the biopsy sample.

# CHAPTER OUTLINE

Etiology and Pathophysiology Clinical Features Diagnosis Treatment Monitoring Prognosis

Glomerulonephritis (GN), or inflammation of the glomeruli and tubules, is the most common type of glomerulonephropathy and is usually caused by immune complexes within the glomerular capillary walls. It is thought to be one of the major causes of chronic kidney disease (CKD) in dogs, and several studies have shown that the prevalence of GN in randomly selected dogs is as high as 50%. The deposition of amyloid within the glomeruli and glomerular basement membrane structural abnormalities (e.g., hereditary Xlinked nephropathy of male Samoyeds and Cocker Spaniels) are additional important, although less common, causes of glomerulonephropathy. Loss of plasma proteins, principally albumin, in the urine is the hallmark of glomerulonephropathy. In addition to its diagnostic utility, the magnitude of proteinuria is associated with progression of CKD, and therefore it has become a major focus in the treatment of patients with glomerulopathies.

## **Etiology and Pathophysiology**

Most glomerulonephropathies in dogs and cats are mediated by immunologic mechanisms. Immune complexes present in the glomerular capillary wall are usually responsible for initiating glomerular damage and proteinuria. For example, soluble circulating antigen-antibody complexes may be deposited or trapped in the glomeruli (Fig. 43-1). In contrast to the glomerular deposition of preformed complexes, immune complexes may also form *in situ* in the glomerular capillary wall (see Fig. 43-1). This occurs when circulating antibodies react with endogenous glomerular antigens or "planted," nonglomerular antigens in the glomerular capil-

lary wall. Nonglomerular antigens may localize in the glomerular capillary wall as a result of an electrical charge interaction or a biochemical affinity with the glomerular capillary wall. Immune complexes have been shown to form *in situ* in dogs with glomerulonephritis associated with dirofilariasis.

Although antibodies directed against intrinsic glomerular basement membrane material have not been found in dogs and cats with naturally occurring glomerulonephritis, several infectious and inflammatory diseases have been associated with immune-mediated glomerular disease (Box 43-1). In many cases, however, the antigen source or underlying disease is not identified; in such cases, the glomerular disease is referred to as *idiopathic*. It is not difficult to identify endogenous immunoglobulin or complement within glomeruli using various immunologic techniques, but the antigens associated with the immune complex within glomerular tissue are rarely identified.

Despite the widespread acceptance of the term *GN*, in most cases glomerular lesions associated with the presence of immune complexes do not have classic evidence of neutrophilic inflammation. In very simplistic terms, the histopathologic changes observed in the glomerulus usually include one or more of the following: cellular proliferation, mesangial matrix expansion, and capillary wall thickening. Additional histopathologic subclassification of glomerular lesions associated with immune complexes that use immunohistochemical and ultrastructural studies will be necessary to improve the ability to effectively treat and accurately prognosticate this disease process.

The glomerulus provides a unique environment for injurious immune complexes to stimulate production of bioactive mediators such as proinflammatory cytokines, vasoactive substances, growth factors, and extracellular matrix proteins and proteases that can contribute to the injury (see Fig. 43-1). These substances may be produced by endogenous glomerular cells or by platelets, macrophages, and neutrophils that are attracted to the immune-mediated lesion. For example, activation of the renin-angiotensin-aldosterone system (RAAS) can have hemodynamic and inflammatory/ fibrotic effects on the kidney. The main hemodynamic effect

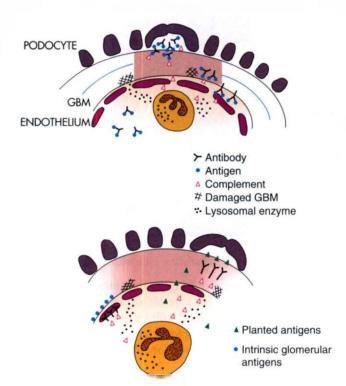

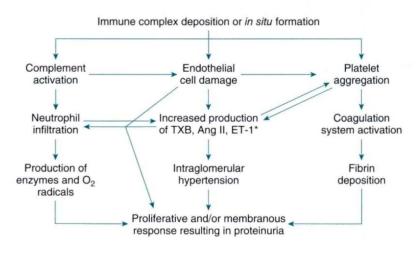

FIG 43-1

The two major types of immunologically mediated glomerular injury. Circulating soluble immune complexes have become trapped in the glomerular filter and have fixed complement. Chemotactic complement components have attracted neutrophils to the area. The release of oxygen free radicals and lysosomal enzymes from neutrophils has resulted in damage to the glomerulus (top). Damage may also result from the attachment of antibodies directed against fixed intrinsic glomerular antigens (bottom, left). Finally, damage may result from the attachment of antibodies directed against planted nonglomerular antigens (bottom, right). GBM, Glomerular basement membrane; PMN, polymorphonuclear leukocyte. (From Chew DJ et al: Manual of small animal nephrology and urology, London, 1986, Churchill Livingstone.)

is vasoconstriction of the efferent glomerular arteriole, resulting in intraglomerular hypertension. This increased hydrostatic pressure within the glomerular capillaries helps drive plasma albumin through the injured glomerular capillary wall. Angiotensin and aldosterone are also proinflammatory and can stimulate glomerular cell proliferation and fibrosis. Aldosterone also stimulates release of plasminogen activator inhibitor 1 (PAI-1), a powerful inhibitor of fibrinolysis that perpetuates glomerular thrombosis (see next paragraph).

In addition to the RAAS, several factors, including activation of the complement system, platelet aggregation, activation of the coagulation system, and fibrin deposition, also contribute to glomerular damage. Platelet activation and aggregation occur secondarily to endothelial damage or antigen-antibody interaction. Platelets, in turn, exacerbate glomerular damage by release of vasoactive and inflammatory substances and by activation of the coagulation cascade. Platelets are also capable of releasing growth-stimulating factors that promote proliferation of vascular endothelial cells. The glomerulus responds to this injury by cellular proliferation, thickening of the glomerular basement membrane, and, if the injury persists, hyalinization and sclerosis (Fig. 43-2). In those cases when identification and correction of an underlying disease process is not possible, treatment is focused on decreasing this glomerular response to the immune complexes (e.g., angiotensin and platelet antagonists).

Once a glomerulus has been irreversibly damaged by GN, the entire nephron becomes nonfunctional. Fibrosis and scarring of irreversibly damaged nephrons may resemble primary interstitial inflammation. In fact, for many years renal interstitial inflammation, or "chronic interstitial nephritis," was thought to be the primary lesion that caused CKD in dogs. As more and more nephrons become involved, glomerular filtration *in toto* decreases. Remaining viable nephrons compensate for the decrease in nephron numbers with increased individual glomerular filtration rates (Fig. 43-3). This "hyperfiltration," coupled with systemic

Nonimmunologic -- hyperfiltration?

Diabetes mellitus

**FIG 43-3**Proposed pathogenesis of progressive loss of nephrons secondary to a primary glomerulonephropathy.

hypertension if present, may further contribute to glomerular hyalinization and sclerosis. Although it has not been documented in dogs with naturally occurring GN, hyperfiltration and proteinuria in remnant nephrons may result in progressive nephron loss, independent of the primary disease process.

Although glomerular amyloidosis is less common than GN, it is a progressive disease that also frequently leads to CKD. It is characterized by the extracellular deposition of nonbranching fibrillar proteins that stack into a specific  $\beta$ -pleated sheet conformation and exhibit green birefringence under polarized light when stained with Congo red (Fig. 43-4). Amyloidosis in dogs and cats is the reactive systemic form, in which amyloid may be deposited in several organs besides the kidneys. Reactive systemic amyloid deposits contain amyloid protein AA, which is an amino-terminal fragment

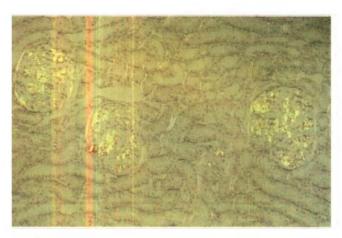

FIG 43-4
Typical appearance of glomerular amyloid (green birefringence) when renal tissue is stained with Congo red and viewed under polarized light.

of the acute-phase reactant protein, serum amyloid A protein (SAA), and is produced by hepatocytes in response to tissue injury. Cytokines (e.g., interleukins, tumor necrosis factor) released from macrophages after tissue injury stimulate hepatocytes to produce SAA. Amyloidosis is usually associated with an underlying inflammatory or neoplastic process; however, no predisposing factors can be identified in many dogs and cats with amyloidosis. Amyloidosis has been associated with cyclic neutropenia and with ciliary dyskinesia and recurrent respiratory tract infections in dogs. Renal amyloidosis is a familial disease in the Abyssinian cat; it results in medullary (not glomerular) amyloid deposition as a part of systemic amyloidosis. A similar form of suspected familial medullary amyloidosis resulting in renal failure has been observed in Chinese Shar-Pei dogs. Intermittent fever that occurs in association with tibiotarsal joint swelling and that resolves regardless of treatment is often observed in these dogs. The staining characteristics of the amyloid in Chinese Shar-Peis indicate that the amyloid is an inflammatory type. This amyloidosis syndrome in Chinese Shar-Peis is similar to that observed in people with familial Mediterranean fever. The medullary deposition of amyloid in Abyssinian cats and Chinese Shar-Pei dogs makes proteinuria uncommon; renal failure, however, is a common sequela.

#### **Clinical Features**

There may be no clinical signs associated with low level proteinuria; alternatively, if signs are present they are usually mild and nonspecific (e.g., weight loss and lethargy). If proteinuria is severe and results in serum albumin concentration <1.5 to 1.0 mg/dl, edema and/or ascites may occur (Table 43-1). If the glomerular disease process causes loss of more than three quarters of the nephrons, clinical signs consistent with advanced stage CKD may be present (e.g., polydipsia-polyuria, anorexia, nausea, vomiting, weight

**TABLE 43-1** 

Signs Associated with Different Manifestations of Glomerular Disease

MANIFESTATION	CLINICAL SIGNS	CLINICOPATHOLOGIC FINDINGS
Mild-to-moderate proteinuria*	Lethargy, mild weight loss, decreased muscle mass	Serum albumin 1.5-3.0 g/dl
Marked proteinuria (>3.5 g/day)	Severe muscle wasting, weight gain may occur, however, as result of edema or ascites	Serum albumin <1.5 g/dl, hypercholesterolemia
Renal failure	Depression, anorexia, nausea, vomiting, weight loss, polyuria- polydipsia	Azotemia, isosthenuria or minimally concentrated urine, hyperphosphatemia, nonregenerative anemia
Pulmonary thromboembolism	Acute dyspnea or severe panting	Hypoxemia; normal or low Pco <sub>2</sub> ; fibrinogen >300 mg/dl; antithrombin <70% of normal
Retinal hemorrhage and/or detachment	Acute blindness	Systolic blood pressure >180 mm Hg

<sup>\*</sup>Microalbuminuria, as discussed in Chapter 42, may precede proteinuria and therefore be an early diagnostic tool. PCO<sub>2</sub>, Partial pressure of carbon dioxide.

loss). Occasionally, clinical signs associated with an underlying infectious, inflammatory, or neoplastic disease may be the reason owners seek veterinary care. Rarely, dogs may be presented with acute dyspnea or severe panting caused by a pulmonary thromboembolism or may have signs associated with thromboembolism elsewhere (e.g., lameness from aortic thromboembolism).

Persistent proteinuria may lead to clinical signs of nephrotic syndrome, which is usually defined as a combination of proteinuria, hypoalbuminemia, ascites or edema, and hypercholesterolemia. Decreased plasma oncotic pressure and hyperaldosteronism activity causing sodium retention are thought to be the primary cause of ascites and edema. It has also been hypothesized that intrarenal mechanisms, independent of aldosterone, may contribute to sodium retention. The hypercholesterolemia associated with the nephrotic syndrome probably occurs because of a combination of decreased catabolism of proteins and lipoproteins and increased hepatic synthesis of proteins and lipoproteins. This results in the accumulation of large-molecular-weight, cholesterol-rich lipoproteins, which are not as easily lost through the damaged capillary wall as are the smallermolecular-weight proteins, such as albumin.

In addition to the previously mentioned clinical signs, systemic hypertension and hypercoagulability are frequent complications in dogs with nephrotic syndrome. A combination of activation of the RAAS and decreased renal production of vasodilators, coupled with increased responsiveness to normal vasopressor mechanisms, are likely involved in the pathogenesis of the systemic hypertension. Systemic hypertension has been commonly associated with immunemediated GN, glomerulosclerosis, and amyloidosis, and in one study, 84% of dogs with glomerular disease were found to be hypertensive. Retinal changes, including hemorrhage, detachment, and papilledema, can be consequences of systemic hypertension; occasionally, blindness may be the presenting sign in hypertensive dogs. In most cases, the systemic hypertension is thought to occur secondary to the kidney disease rather than being a primary entitiy that causes the kidney disease. Systemic hypertension can be transmitted into the glomerular capillaries, especially as autoregulation fails, resulting in intraglomerular hypertension. This increased hydrostatic pressure within glomerular capillaries can exacerbate loss of plasma proteins across the already abnormal capillary wall or sufficiently damage the wall to induce nascent glomerular protein loss. Blood pressure measurement should be part of the evaluation and management of dogs with glomerular disease because it is likely that control of systemic hypertension may slow the progression of glomerular disease.

Hypercoagulability and thromboembolism associated with the nephrotic syndrome occur secondarily to several abnormalities in hemostasis. In addition to mild thrombocytosis, a hypoalbuminemia-related platelet hypersensitivity increases platelet adhesion and aggregation proportionally to the magnitude of hypoalbuminemia. Loss of antithrombin (AT) in urine also contributes to hypercoagulability.

Antithrombin works in concert with heparin to inhibit serine proteases (clotting factors II, IX, X, XI, and XII) and normally plays a vital role in modulating thrombin and fibrin production. Finally, impaired fibrinolysis caused by aldosterone-induced production of PAI-1 further enhances blood clotting. The pulmonary arterial system is the most common location for a thromboembolic disease in dogs with glomerular lesions. Dogs with pulmonary thromboembolism are usually dyspneic and hypoxemic and have minimal pulmonary parenchymal radiographic abnormalities. Treatment of pulmonary thromboembolism is difficult, often expensive, and frequently unrewarding; therefore early prophylactic treatment to prevent thrombus formation is important.

There is increasing suspicion that proteinuria may cause glomerular and tubulointerstitial damage that can lead to progressive nephron loss in dogs and cats. Plasma proteins that have crossed the glomerular capillary wall can accumulate within the glomerular tuft and stimulate mesangial cell proliferation and increased production of mesangial matrix. In addition, excessive amounts of protein in the glomerular filtrate can damage tubular epithelial cells and lead to interstitial inflammation, fibrosis, and cell death. Mechanisms for the tubulointerstitial lesions associated with proteinuria include tubular cell lysosomal damage/rupture, peroxidative and immune-mediated damage, increased production of growth factors, cytokines and vasoactive agents, and transdifferentiation of tubular cells to myoepithelial cells that can produce collagen.

In dogs with naturally occurring CKD, proteinuria resulting in a urine protein: creatinine ratio ≥1.0 was associated with a threefold greater risk of developing uremic crises and death compared with dogs with urine protein: creatinine ratio < 1.0. The relative risk of adverse outcome was approximately 1.5 times higher for every 1 unit increase in urine protein: creatinine ratio. In addition, dogs with urine protein:creatinine ratio ≥1.0 had a decrease in renal function that was greater in magnitude than that observed in dogs with urine protein: creatinine ratio <1.0. In cats with naturally occurring CKD, proteinuria appears to be very highly related to survival. The hazard ratios (95% confidence intervals) for death or euthanasia were 2.9 and 4.0 for urine protein: creatinine ratio 0.2 to 0.4 and >0.4, respectively, compared with the baseline group with a urine protein: creatinine ratio <0.2. On the basis of this evidence, it is possible that proteinuria is not only a marker of CKD in the dog and cat but also a mediator of progressive renal injury. Attenuation of proteinuria should be a major treatment objective in dogs and cats with CKD.

# Diagnosis

Persistent, severe proteinuria with a normal urine sediment (hyaline casts may be observed) is the hallmark clinicopathologic sign of glomerulonephropathies. The urine protein: creatinine ratio is used to quantify the magnitude of the urine protein loss. Microalbuminuria may precede overt proteinuria in many cases (see the section on proteinuria in Chapter 42). Protein-losing nephropathies are definitively diagnosed on the basis of renal cortical histopathologic findings. (See sections on proteinuria and renal biopsy in Chapters 41 and 42.)

#### **Treatment**

Inasmuch as immune complexes usually initiate GN, primary treatment objectives include (1) identification and elimination of causative/associated antigens and (2) reduction of the glomerular response to the immune complexes.

Elimination of the source of antigenic stimulation is the treatment of choice for GN. For example, proteinuria associated with dirofilariasis in dogs often improves or resolves after successful treatment of parasitic infection. Unfortunately, elimination of the antigen source often is not possible because the antigen source or underlying disease may not be identified or may be impossible to eliminate (e.g., neoplasia). In a retrospective study by Cook (1996) of 106 dogs with GN, 43% had no identifiable concurrent disease or disorder and 19% had neoplasia. Infection, polyarthritis, hepatitis, hyperadrenocorticism, and immune-mediated hemolytic anemia are additional commonly identified concurrent medical problems (Box 43-2).

Immunosuppressive drugs have been recommended in dogs with GN, but despite these recommendations, there has been only one controlled clinical trial in veterinary medicine assessing the effects of immunosuppressive treatment. In this

BOX 43-2

Treatment Guidelines for Dogs and Cats with Glomerulonephritis

- 1. Identify and eliminate any underlying diseases
- Immunosuppressive treatment (usually not recommended for dogs)
  - a. Cyclophosphamide, 50 mg/m² PO q48h (dogs) or 200 to 300 mg/m² PO q3wk (cats) or
  - b. Azathioprine,  $50 \text{ mg/m}^2 \text{ PO } \text{ q}24\text{h} \times 7 \text{ days, then } \text{q}48\text{h} \text{ (dogs only) or}$
  - c. Cyclosporine A, 15 mg/kg PO q24h (dogs only)
  - d. Prednisone, 1.0 to 2.0 mg/kg PO q12-24h (cats only)
- Antiinflammatory-hypercoagulability treatment: aspirin, 0.5 to 5.0 mg/kg PO q12h (dogs); 0.5 to 5.0 mg/kg PO q48h (cats)
- Supportive care
  - Dietary: sodium restriction, high-quality-low-quantity protein
  - b. Hypertension: dietary sodium reduction; ACEIs (e.g., enalapril, 0.5 mg/kg PO q12-24h, or benazepril, 0.25 to 0.5 mg/kg PO q24h; ACEIs often have antiproteinuric effects as well) and/or calcium channel blockers
  - Edema and ascites: dietary sodium restriction; furosemide, 2.2 mg/kg PO q8-24h, if necessary

study by Vaden (1995) cyclosporine treatment was found to be of no benefit in reducing proteinuria associated with GN in dogs. The association between hyperadrenocorticism or long-term exogenous corticosteroid administration and GN and thromboembolism in the dog, as well as the lack of consistent therapeutic response to corticosteroids, raises questions about use of these drugs in dogs with GN. In a retrospective study of dogs with naturally occurring GN, treatment with corticosteroids appeared to be detrimental, leading to azotemia and worsening of proteinuria. Similarly, prednisone increased the urine protein: creatinine level from 1.5 to 5.6 in carrier female dogs with X-linked hereditary nephropathy. Consequently, routine use of corticosteroids to treat GN in dogs is not recommended. Treatment with corticosteroids may be indicated, however, if the underlying disease process is known to be steroid responsive (e.g., systemic lupus erythematosus). It is likely that there are specific subtypes of canine immune complex GN (e.g., minimal change GN) that are steroid responsive if they are appropriately identified and treated.

If an underlying or concurrent disease process cannot be identified and treated, or if immunosuppressive treatment is deemed inappropriate, treatment may be aimed at decreasing the glomerular response to the presence of immune complexes. Platelets appear to play an important role in the glomerular response to immune complexes, and therefore aspirin treatment is often recommended. Appropriate dosage is probably important if nonspecific cyclooxygenase inhibitors, such as aspirin, are used to decrease glomerular inflammation and platelet aggregation. An extremely low dosage of aspirin (0.5 mg/kg administered orally once a day) may selectively inhibit platelet cyclooxygenase without preventing the beneficial effects of prostacyclin formation (e.g., vasodilation, inhibition of platelet aggregation). Low-dose aspirin is easily administered on an outpatient basis and does not require extensive monitoring. Because fibrin accumulation within the glomerulus is a frequent and irreversible consequence of GN and thromboembolic disorders can complicate the management of protein-losing nephropathies, antiplatelet/anticoagulant treatment with aspirin may serve several purposes.

Treatment with angiotensin-converting enzyme inhibitors (ACEIs) can reduce proteinuria and slow disease progression. In dogs with unilateral nephrectomy and experimentally induced diabetes mellitus, ACEI administration reduced glomerular transcapillary hydraulic pressure and glomerular cell hypertrophy as well as proteinuria. In another study by Grodecki (1997) ACEI treatment of Samoyed dogs with Xlinked hereditary nephritis decreased proteinuria, improved renal excretory function, decreased glomerular basement membrane splitting, and prolonged survival compared with control dogs. A double-blind, multicenter, prospective clinical trial assessed the effects of enalapril (EN) versus standard care in dogs with naturally occurring, idiopathic GN. The enalapril treatment group had decreased proteinuria, systolic blood pressure, and stable renal function compared with the placebo-treated group. In prospective randomized, controlled clinical trials (King, 2006; Mizutani, 2006) in cats with spontaneous CKD, benazepril has been shown to reduce proteinuria, delay CKD progression, and extend survival time.

Treatment with ACEI probably decreases proteinuria and preserves renal function associated with glomerular disease by several mechanisms. In dogs administration of lisinopril decreases efferent glomerular arteriolar resistance, which results in decreased glomerular transcapillary hydraulic pressure and decreased proteinuria. In rats administration of EN prevents the loss of glomerular heparan sulfate that can occur with glomerular disease. Administration of ACEI also is thought to attenuate proteinuria by decreasing the size of glomerular capillary endothelial cell pores in people. In addition, the antiproteinuric and renal protective effects of ACEI in people may be, in part, associated with improved lipoprotein metabolism. Decreased production of angiotensin and aldosterone may also result in decreased renal fibrosis. Finally, administration of ACEI in dogs slows glomerular mesangial cell growth and proliferation that can alter the permeability of the glomerular capillary wall and lead to glomerulosclerosis.

Supportive therapy is important in the management of dogs with GN and should be aimed at alleviating systemic hypertension, decreasing edema/ascites, and reducing the risk of thromboembolism. ACEIs are recommended as the first line of treatment for proteinuric, hypertensive dogs. In those cases wherein systemic hypertension is refractory to ACEI treatment, a calcium channel blocker should be added to the antihypertensive regimen. Although similar studies have not been performed in dogs or cats, in people the combination of ACEI and an aldosterone receptor antagonist (e.g., spironolactone) have had additive effects in reducing proteinuria and renal disease progression.

Cage rest and restriction of dietary sodium should be the primary treatment considerations for patients with edema and/or ascites. Paracentesis and diuretics should be reserved for those dogs with respiratory distress or abdominal discomfort. Overzealous use of diuretics may cause dehydration and acute renal decompensation. Plasma transfusions will provide only temporary benefit in terms of increasing oncotic pressure resulting from the addition of albumin. In the past, dietary protein supplementation was recommended to offset the effects of proteinuria and reduce edema and ascites; however, recent studies in proteinuric heterozygous female dogs with X-linked nephropathy suggest that reduced dietary protein is associated with reduced proteinuria. N-3 fatty acid supplementation may also be beneficial; in dogs with surgically reduced remnant kidneys, dietary supplementation with fish oil reduced proteinuria, intraglomerular pressures, and glomerular lesion and maintained the glomerular filtration rate.

Similar to the treatment of GN, the primary treatment for amyloidosis, if possible, should be the identification and treatment of any underlying inflammatory process. Dimethylsulfoxide (DMSO) has been shown to dissolve amyloid fibrils *in vitro* and *in vivo* in mice. It has been hypothesized

that DMSO has a similar amyloid-dissolving effect in domestic animals. The antiinflammatory effects of DMSO may also serve to decrease production of the acute-phase reactant SAA and the inflammation associated with an underlying disease. Decreased urinary protein excretion was observed in one dog with amyloidosis treated with DMSO; however, the effects of DMSO were difficult to determine because two potential underlying causes (interdigital pyoderma and a Sertoli cell tumor) were eliminated before the DMSO treatment. The dosage of DMSO used in that dog was 80 mg/kg administered subcutaneously three times per week; the treatment was continued for more than a year without apparent adverse effects. Other studies assessing the effects of DMSO in dogs with amyloidosis, however, have shown the treatment to be ineffective.

Colchicine is another drug that is frequently mentioned for the treatment of amyloidosis. It prevents the production of SAA by hepatocytes and has been shown to prevent amyloidosis in humans and mice if used early in the disease. Although colchicine has been recommended to prevent medullary amyloidosis in Chinese Shar-Pei dogs with fever and tibiotarsal joint swelling, no controlled studies of its use in this setting have been performed. The dosage of colchicine that has been recommended for the prophylactic treatment of amyloidosis is 0.025 mg/kg given orally q24h. Increasing the dose to 0.025 mg/kg, given orally q12h, may be considered if the animal tolerates the initial dose well for 2 weeks. However, because adverse effects of colchicine include bone marrow toxicity, the patient should be monitored closely with periodic complete blood counts.

# Monitoring

It is important to monitor the urine protein: creatinine ratio after initiating treatment. Immunosuppressive treatment could alter the ratio of antigen to antibody, thus exacerbating the glomerular lesions and the proteinuria (i.e., a decrease in antibody formation leading to a mild excess of antigen or equal amounts of antigen and antibody in the immune complexes), in which case treatment should be altered or discontinued. In addition, corticosteroids can induce proteinuria owing to a number of mechanisms, so an increase in the urine protein: creatinine ratio can be iatrogenic, not necessarily a result of the progression of the disease. Lack of response to ACEI treatment may suggest the need for increasing the dosage or adding one or more drugs.

In addition, blood pressure and serum creatinine and urea nitrogen concentrations should be monitored in animals with GN. In cases in which the glomerular filtration rate depends on sodium retention and volume expansion, treatment with ACEIs can be associated with a decrease in renal excretory function. Finally, although proteinuria then occurs before the onset of azotemia, GN can lead to CKD. With the development of CKD, the glomerular filtration rate decreases and the proteinuria therefore usually also decreases. Management guidelines for CKD are presented in Chapter 44.

## **Prognosis**

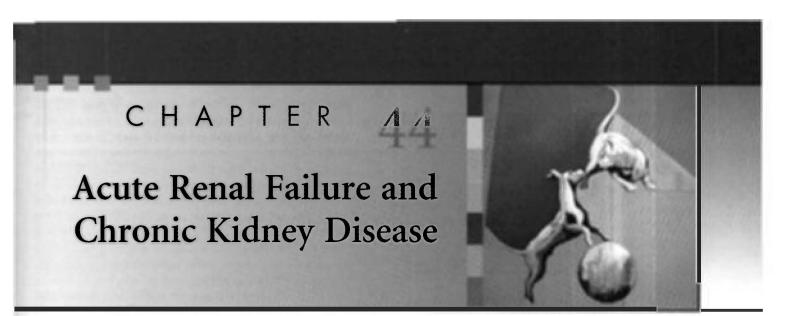

The prognosis for dogs with GN is variable and is best based on consideration of the following factors: severity of dysfunction (i.e., the magnitude of the proteinuria and the presence or absence of azotemia), the response to therapy, and the assessment of renal histopathology. Clinical experience suggests that the disease is progressive in many cases, but decreases in the urine protein: creatinine ratio and increases in albumin and AT concentration can occur in dogs with immune-mediated GN treated with diet, ACEIs, and low-dose aspirin. In selected cases, immunosuppressive treatment with corticosteroids and azathioprine may be of benefit.

Inasmuch as glomerular amyloid deposition results in severe proteinuria, with its attendant effects, the disease is relentlessly progressive, often resulting in CKD and uremia; and given that no specific treatment has proved to be effective, the prognosis for animals with renal amyloidosis is guarded to poor.

# CHAPTER OUTLINE

# **ACUTE RENAL FAILURE**

Etiology and Pathogenesis Clinical Features and Diagnosis Risk Factors for Acute Renal Damage/Failure Monitoring Patients at Risk for Acute Renal Damage/ Failure

Treatment of Established Acute Renal Failure CHRONIC KIDNEY DISEASE

Etiology and Pathogenesis Clinical Features and Diagnosis Staging Chronic Kidney Disease Further Diagnostics and Treatment

Renal failure occurs when approximately three fourths of the nephrons of both kidneys cease to function. Acute renal failure (ARF) results from an abrupt decline in renal function and is usually caused by an ischemic or toxic insult to the kidneys, although leptospirosis is reemerging as an important infectious cause of ARF. Ischemic or toxicantinduced injury usually results in damage to the metabolically active epithelial cells of the proximal tubules and thick ascending loop of Henle, causing impaired regulation of water and solute balance. Nephrotoxicants interfere with essential tubular cell functions and cause cellular injury, swelling, and death. Renal ischemia causes cellular hypoxia and substrate insufficiency, which leads to the depletion of adenosine triphosphate (ATP), cellular swelling, and death. Vasoconstriction secondary to toxic or ischemic tubular epithelial injury further decreases glomerular filtration. It is important to note, however, that tubular lesions and dysfunction caused by toxic and ischemic insults may be reversible. In contrast, the nephron damage associated with chronic kidney disease (CKD) is usually irreversible. Regardless of whether the underlying disease primarily affects the glomeruli, tubules, interstitium, or renal vasculature, irreversible damage to any portion of the nephron renders the entire nephron nonfunctional. Irreversibly damaged nephrons are replaced by fibrous connective tissue; therefore a specific cause is rarely determined once end-stage kidney damage is present. CKD occurs over a period of weeks, months, or years and is a leading cause of death in dogs and cats. Once advanced stage CKD has occurred, improving renal function is usually not possible. The goal of CKD treatment is three-fold: (1) to identify and correct the primary disease process, (2) to monitor and slow disease progression, and (3) to alleviate patient clinical signs.

Many different and sometimes confusing terms are used to describe renal function and its deterioration (Fig. 44-1):

- *Renal disease* implies the existence of renal lesions; it does not qualify the cause, severity, or distribution of the lesions or the degree of renal function.
- *CKD* refers to a loss of nephrons associated with prolonged (usually longer than 2 months) and often progressive disease process.
- Renal reserve may be thought of as the percentage of "extra" nephrons available (i.e., those not necessary to maintain normal renal function). Although it probably varies from animal to animal, it is greater than 50% in normal cats and dogs.
- Renal insufficiency begins when the renal reserve is lost.
   Animals with renal insufficiency outwardly appear normal but have a reduced capacity to compensate for stresses such as infection or dehydration and have reduced ability to concentrate urine.
- Azotemia is the increased concentration of urea nitrogen, creatinine, and other nonproteinaceous nitrogenous waste products in the blood.
- Renal azotemia denotes azotemia caused by renal parenchymal lesions.
- Renal failure is a state of decreased renal function that allows persistent abnormalities (azotemia and inability to concentrate urine) to exist; it refers to a level of organ function rather than a specific disease entity.
- Uremia is the presence of all urine constituents in the blood. It may occur secondary to renal failure or postrenal disorders, including urethral obstruction and urinary bladder rupture.

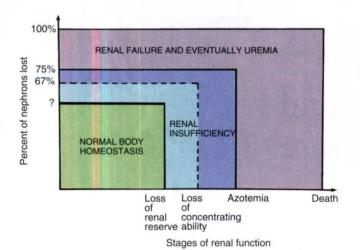

FIG 44-1
The stages of renal function. (From Grauer G et al: Chronic renal failure in the dog, Compend Contin Educ Pract Vet 3:1009, 1981.)

BOX 44-

Factors that May Predispose the Kidney to Ischemia and Toxicant-Induced Injury

The kidneys receive 20% of cardiac output; the cortex receives 90% of the renal blood flow.

The glomerular capillaries have a large surface area.

Proximal tubule and thick ascending loop of Henle cells have a high metabolic rate and are susceptible to hypoxia and nutrient deficiency.

Tubular secretion and resorption may concentrate toxicants within cells.

A countercurrent multiplier system may concentrate toxicants within the medulla.

Xenobiotic metabolism within the kidney may generate toxic metabolites (e.g., metabolism of ethylene glycol).

The *uremic syndrome* is a constellation of clinical signs (e.g., gastroenteritis, acidosis, pneumonitis, osteodystrophy, and encephalopathy) that occur secondary to uremia.

#### **ACUTE RENAL FAILURE**

## **Etiology and Pathogenesis**

The kidneys are highly susceptible to the effects of ischemia and toxicants because of their unique anatomic and physiologic features (Box 44-1). For example, the large renal blood flow (approximately 20% of the cardiac output) results in the increased delivery of blood-borne toxicants to the kidney, as compared with that to other organs. The renal cortex is especially susceptible to toxicants because it receives 90% of the renal blood flow and contains the large endothelial

surface area of the glomerular capillaries. Within the renal cortex, the epithelial cells of the proximal tubule and thick ascending loop of Henle are most frequently affected by ischemia and toxicant-induced injury because of their transport functions and high metabolic rates. Toxicants disrupt the metabolic pathways that generate ATP, and ischemia can rapidly deplete cellular ATP stores. With the resulting loss of energy, the sodium-potassium pump (Na/K) fails, leading to cell swelling and death. By resorbing water and electrolytes from the glomerular filtrate, tubular epithelial cells may be exposed to increasingly higher concentrations of toxicants. Toxicants that are either secreted or resorbed by tubular epithelial cells (e.g., gentamicin) may accumulate in high concentrations within these cells. Similarly, the countercurrent multiplier system may concentrate toxicants in the medulla. Finally, the kidneys also play a role in the biotransformation of many drugs and toxicants. This usually results in the formation of metabolites that are less toxic than the parent compound; however, in some cases (e.g., the oxidation of ethylene glycol to glycolate and oxalate), the metabolites are more toxic than the parent compound.

Box 44-2 presents a partial list of potential nephrotoxicants. It should be noted that toxic insults to the kidney often can be caused by therapeutic agents, in addition to the better-known nephrotoxicants. Gentamicin and ethylene glycol are two of the most common causes of toxicantinduced ARF. Box 44-3 presents a partial list of ischemic causes of ARF. Leptospirosis is a common cause of ARF; the organisms colonize and proliferate within renal tubular epithelial cells and can lead to acute interstitial nephritis. Acute renal damage leading to failure can also occur in dogs with leptospirosis because of renal vasculitis and the development of swelling that further compromises renal blood flow. Acute renal failure has also recently been associated with ingestion of pet food containing contaminated wheat and corn gluten and rice protein concentrates. The investigation has focused on melamine and cyanuric acid as the major contaminants; however, melamine-related substances (e.g., ammelide and ammeline) may also be involved in the pathogenesis. It is thought that a chemical reaction between melamine and cyanuric acid produces insoluble crystals that form in the distal renal tubules of affected animals, compromising renal function. Clinical presentation is quite variable and ranges from severe ARF to mild azotemia associated with urineconcentrating deficits to no clinical signs. Crystalluria (round, yellow crystals with radiant striations that may resemble urate crystals) is observed in many cases. Identification of the crystals can be accomplished at veterinary diagnostic laboratories. Treatment of affected patients in largely symptomatic, long-term intravenous (IV) fluid therapy may be required for recovery in some cases.

In many cases, ARF inadvertently develops in the hospital setting in conjunction with the performance of diagnostic or therapeutic procedures. For example, ARF may be caused by hypotension and decreased renal perfusion associated with anesthesia and surgery or with the use of vasodilators or nonsteroidal antiinflammatory drugs (NSAIDs). Prolonged

# Partial List of Potential Causes of Decreased Renal Perfusion/Ischemia in Dogs and Cats

Dehydration

Hemorrhage

Hypovolemia

Decreased oncotic pressure

Deep anesthesia

Increased blood viscosity

Sepsis

Shock/vasodilation

Administration of nonsteroidal antiinflammatory agents, decreased renal prostaglandin formation

Hyperthermia

Hypothermia

Burns

Trauma

Renal vessel thrombosis or microthrombus formation Transfusion reactions anesthesia with inadequate fluid therapy in older dogs and cats with preexisting, subclinical renal insufficiency is a frequent cause of renal ischemia and ARF in the hospital setting. Similarly, ARF frequently occurs in animals treated with potential nephrotoxicants such as gentamicin or amphotericin. The kidneys can maintain adequate renal perfusion pressure by autoregulation as long as the mean arterial blood pressure exceeds approximately 60 to 70 mm Hg. Renal blood flow and perfusion pressure must be maintained for glomerular filtration and cellular delivery of oxygen and nutrients to occur. Cellular swelling secondary to decreased Na/K pump activity results from the osmotic extraction of water from the extracellular space, causing the amount of water in the plasma to decrease. The consequences of a decreased amount of plasma water in the renal vasculature are red blood cell aggregation and vascular congestion and stasis, which tend to potentiate and perpetuate decreased glomerular blood flow and decreased oxygen and nutrient delivery. The common result of ischemic or toxicant-induced tubular cell swelling, injury, and death is nephron dysfunction leading to a decreased glomerular filtration rate

In ARF dysfunction and reduced glomerular filtration occur at the individual nephron level as a result of a combination of tubular obstruction, tubular backleak, renal arte-

riolar vasoconstriction, and decreased glomerular capillary permeability. Specifically, cellular debris within the tubule may inspissate and obstruct the flow of filtrate through the nephron. Alternatively, interstitial edema may compress and obstruct renal tubules. A backleak, or abnormal reabsorption of filtrate, occurs because of a loss of tubular cell integrity, allowing the filtrate to cross from the tubular lumen into the renal interstitium and subsequently the renal vasculature. Tubular backleak is facilitated by tubular obstruction because of the increased intratubular pressures proximal to the obstruction. The decreased resorption of solute and water by damaged proximal tubule segments results in the increased delivery of solutes and fluid to the distal nephron and macula densa in many nephrons, which causes afferent glomerular arteriole constriction. The exact mediators of this vasoconstriction are not known, but natriuretic factor, the reninangiotensin system, and thromboxane may be involved. A decrease in the permeability of the glomerular capillary wall also leads to a reduction in glomerular filtration. For example, aminoglycosides have been shown to decrease both the number and size of fenestrae in glomerular capillary endothelial cells, thereby decreasing the surface area available for ultrafiltration. The impaired glomerular capillary permeability that occurs in ARF often persists after vasoconstriction and renal blood flow have been corrected.

Acute tubular damage leading to ARF has three distinct phases: (1) initiation, (2) maintenance, and (3) recovery. During the initiation phase, therapeutic measures that reduce the renal insult can prevent the development of established ARF. In the initiation phase, individual tubules are damaged but overall renal function remains adequate. Acute tubular damage, occurring before the development of ARF, is suggested by renal tubular epithelial cells and casts in the urine sediment (discussed in more detail later). The maintenance phase is characterized by the development of tubular lesions and nephron dysfunction (i.e., renal azotemia and urineconcentrating deficits). Although therapeutic interventions during the maintenance phase are often life saving, they usually do little to diminish the severity of existing renal lesions, improve function, or hasten recovery. In the recovery phase, renal lesions are repaired and function improves. Tubular damage may be reversible if the tubular basement membrane is intact and viable epithelial cells are present. Although new nephrons cannot be produced and irreversibly damaged nephrons cannot be repaired, the functional hypertrophy of surviving nephrons may adequately compensate for the decrease in nephron numbers. Even if renal functional recovery is incomplete, adequate function may be reestablished.

# **Clinical Features and Diagnosis**

Clinical signs of ARF are often nonspecific and include lethargy, depression, anorexia, vomiting, diarrhea, and dehydration; occasionally, uremic breath or oral ulcers may be present. A diagnosis of ARF is suspected if azotemia develops acutely and is associated with persistent isosthenuria or minimally concentrated urine. Prerenal dehydration and

FIG 44-2

Ultrasonographic appearance of a kidney from a dog that ingested ethylene glycol. Notice the markedly increased renal cortical echogenicity. (Courtesy Dr. Phillip Steyn, Colorado State University, Fort Collins, Colo.)

azotemia superimposed on an inability to concentrate urine (e.g., Addison's disease, hypercalcemia, overzealous use of furosemide) initially mimics renal failure; however, in these prerenal cases, volume replacement results in resolution of the azotemia.

ARF occurs within hours or days of exposure to the insult. Unique clinical signs and clinicopathologic findings associated with ARF include enlarged or swollen kidneys, hemoconcentration, good body condition, active urine sediment (e.g., granular casts, renal epithelial cells), and relatively severe hyperkalemia and metabolic acidosis (especially in the face of oliguria; see Box 41-7). Clinical signs in an animal with ARF tend to be severe compared with those seen in an animal with CKD and similar magnitude of azotemia. Renal ultrasonographic findings in dogs and cats with ARF are usually nonspecific, with diffusely normal to slightly hypoechoic renal cortices. In animals with calcium oxalate nephrosis associated with ethylene glycol ingestion, the renal cortices can be very hyperechoic (Fig. 44-2). Doppler estimation of the resistive index (RI) in renal arcuate arteries is increased in many dogs with ARF; however, this method of evaluation must be more extensively correlated with the renal histopathologic changes before firm conclusions regarding the merits of the RI can be drawn.

Renal biopsy specimens from dogs and cats with ARF show proximal tubular cell degeneration, ranging from cloudy swelling to necrosis, with edema and mononuclear and polymorphonuclear leukocyte infiltration in the interstitium. Ethylene glycol and melamine-associated nephrotoxicity is frequently associated with intratubular crystals. Although toxicant-induced ARF cannot be histopathologically differentiated from ARF caused by ischemia in all cases, renal histologic findings are often helpful in establishing a prognosis. Evidence of tubular regeneration (e.g., flattened, basophilic epithelial cells with irregular nuclear size; mitotic figures; high nuclear/cytoplasmic ratios) and the finding of generally intact tubular basement membranes are good

prognostic findings and may be observed as early as three days after the insult. Conversely, large numbers of granular casts, extensive tubular necrosis, and interstitial mineralization and fibrosis with disrupted tubular basement membranes are poor prognostic signs. In addition to the renal histopathologic changes, the degree of functional impairment and, even more important, the response to therapy should be considered when formulating a prognosis.

# RISK FACTORS FOR ACUTE RENAL DAMAGE/FAILURE

Although the prevention of trauma (e.g., being hit by car) that may lead to shock and the development of renal ischemia or exposure to nephrotoxicants outside the hospital relies on client education and environmental control, an important aspect of the prevention of hospital-acquired ARF is the identification of patients at increased risk. Several risk factors that predispose dogs to the development of gentamicin-induced ARF have been identified (Box 44-4); however, it is likely that many of these factors also predispose dogs and cats to the development of other types of toxicantinduced ARF as well as ARF induced by ischemia. In many cases a combination of decreased renal perfusion or treatment with nephrotoxic agents in the context of more chronic, preexisting risk factors is responsible for the development of ARF in the hospital setting. Once the clinician detects predisposing risk factors, he or she can assess the risk: benefit ratio in individual cases in which an elective anesthetic procedure is considered or treatment with potentially nephrotoxic drugs is indicated. In some situations, predisposing risk factors can be eliminated or corrected before any potential renal insults occur.

Major categories of risk factors include disorders affecting renal perfusion, preexisting renal disease, electrolyte disturbances, treatment with nephrotoxic drugs, and dietary influences. Poor renal perfusion increases the risk of neph-

BOX 44-4

#### Risk Factors for Acute Renal Failure

Preexisting renal disease or renal insufficiency

Dehydration

Decreased cardiac output

Sepsis, pyometra

Disseminated intravascular coagulation (DIC)

Fever

Liver disease

Electrolyte abnormalities such as hypokalemia and hypercalcemia

Concurrent use of diuretics with potentially nephrotoxic drugs such as aminoglycosides

Concurrent use of potentially nephrotoxic drugs such as aminoglycosides, nonsteroidal antiinflammatory drugs, and intravenous radiographic contrast agents

Decreased dietary protein

Diabetes mellitus

rotoxic and ischemic damage to the kidney. Dehydration and volume depletion are perhaps the most common causes of decreased renal perfusion. Renal hypoperfusion can also be caused by decreased cardiac output, decreased plasma oncotic pressure, increased blood viscosity, or systemic vasodilation. In addition to decreased renal perfusion, volume depletion also leads to a decreased volume of distribution of nephrotoxic drugs and a decreased flow of tubular fluid. Decreased tubular flow, in turn, potentiates tubular resorption, which can increase the intratubular concentration of nephrotoxicants. Preexisting renal disease and advanced age, which is often associated with some degree of decreased renal function, may increase the potential for nephrotoxicity produced by several mechanisms. For example, the pharmacokinetics of potentially nephrotoxic drugs may be altered in the face of decreased renal function. Specifically, the excretion of gentamicin has been shown to be decreased in partially nephrectomized dogs with subclinical renal dysfunction. Animals with renal insufficiency or advanced age may also have reduced urine-concentrating ability and thus a decreased ability to compensate for dehydration. Preexisting renal disease may also compromise the production of vasodilatory prostaglandins. The resulting unbalanced vasoconstriction could result in decreased renal perfusion.

Studies in dogs have shown that reduced dietary potassium intake exacerbates gentamicin-induced nephrotoxicity, possibly because potassium-depleted cells are more susceptible to necrosis. It is important to note that an adverse effect of high-dose gentamicin treatment in dogs is an increase in the urinary excretion of potassium. It is possible that this could result in potassium depletion (especially if it occurs in combination with anorexia or vomiting) and thus increase the risk of gentamicin-induced nephrotoxicity. Because potassium is primarily an intracellular cation, any patient with prolonged anorexia, vomiting, or diarrhea may have whole-body potassium depletion even if serum potassium concentrations are within the normal range.

The administration of potentially nephrotoxic drugs or drugs that may enhance nephrotoxicity obviously increases the risk of ARF. For example, the concurrent use of furosemide and gentamicin in dogs is associated with an increased risk of ARF and an increased severity of ARF, should it occur. Furosemide probably potentiates gentamicin-induced nephrotoxicity by causing dehydration, reducing the volume of distribution of gentamicin, and increasing its renal cortical uptake. Fluid repletion minimizes but does not negate the additive effect of furosemide on gentamicin-induced nephrotoxicity in the dog because furosemide facilitates the tubular uptake of gentamicin independent of hemodynamic changes. By means of similar mechanisms, furosemide has been shown to enhance radiocontrast agent and cisplatin-induced nephrotoxicity in human beings.

The use of NSAIDs can also increase the risk of acute renal damage and ARF. In well-hydrated, healthy patients, NSAIDs are usually well tolerated. However, in situations associated with high renin concentration (e.g., sodium or volume depletion, hypotension, congestive heart failure, CKD) the potential for adverse effects on renal function increases. High renin states stimulate the production of angiotensin and aldosterone, which can, in turn, decrease renal blood flow and GFR. Normally, renal prostaglandins counteract this decrease in renal blood flow and GFR. However, in patients with CKD and those undergoing treatment with NSAIDs, the protective effects that prostaglandin has on renal blood flow and GFR may be compromised. Dogs appear to be particularly sensitive to NSAIDs such as ibuprofen and naproxen, which, in addition to ARF, may cause gastrointestinal tract ulceration. At one time, COX 2-specific inhibitors were thought to have less effect on renal blood flow; however, research shows that COX 2 enzymes are present or expressed in the canine kidney; therefore any NSAID, regardless of its COX specificity or sparing properties, has the potential to produce adverse renal effects. In particular, dogs express higher basal levels of COX 2 in the kidney than some other species and may be uniquely sensitive to the nephrotoxic effects of COX 2-selective drugs. There is also the concern that patients treated with angiotensin-converting enzyme inhibitors (ACEIs) may have increased risk of renal toxicity when treated with NSAIDs because some of the beneficial effects of ACEI are derived from kinin-stimulated production of prostaglandins. In one study of normal dogs treated with enalapril and tepoxalin, no alteration of GFR was noted.

Studies in healthy dogs have shown that the quantity of protein fed before a nephrotoxic insult can significantly affect the degree of renal damage and dysfunction. Highdietary-protein (27.3%) conditioning beginning 21 days before and continuing during gentamicin administration was found to reduce nephrotoxicity, enhance gentamicin clearance, and result in a larger volume of distribution compared with the findings in dogs fed medium (13.7%) or low levels of protein (9.4%). In addition, creatinine clearance and the renal elimination of gentamicin were preserved throughout 7 days of treatment in dogs fed a high-protein diet, whereas these parameters decreased during the treatment period in dogs fed a medium- or low-protein diet. Although dietary protein conditioning may not be practical in the clinical setting, it is important to realize that anorectic animals may be at increased risk for ARF as a result of decreased protein intake.

Risk factors are additive, and any complication occurring in high-risk animals increases the potential for ARF. By virtue of their diseases, animals in shock or with acidosis, sepsis, or major organ system failure are at increased risk for ARF, and these are also the animals that are likely to require anesthesia or chemotherapy, which is potentially damaging to the kidneys. For example, ARF is common in dogs with pyometra and *Escherichia coli* endotoxin-induced urine-concentrating defects. If fluid therapy is inadequate during anesthesia for ovariohysterectomy or during the recovery period, dehydration and decreased renal perfusion may result in ARF. Trauma, extensive burns, pancreatitis, diabetes mellitus, and multiple myeloma are examples of disorders associated with a high incidence of ARF in people. Addi-

tional clinical conditions that are thought to enhance the risk of ARF in dogs include vasculitis, fever, and prolonged anesthesia.

# MONITORING PATIENTS AT RISK FOR ACUTE RENAL DAMAGE/FAILURE

The recognition and appropriate management of renal injury in the initial phase of ARF are associated with improvement in prognosis; therefore animals receiving potentially nephrotoxic drugs and high-risk animals undergoing anesthesia should be monitored closely.

Along with blood pressure, urine production is an excellent parameter to monitor during anesthesia. Ideally, urine production should be greater than 2 ml/kg/h. Increased urinary excretion of protein, glucose (normoglycemic glucosuria), or casts and/or renal tubular epitheial cells may be an early indication of renal tubular damage in animals receiving potentially nephrotoxic drugs. As an alternative to standard clinicopathologic tests, the detection and quantification of urine enzymes (enzymuria) have been used to recognize early nephrotoxicity in the dog. Inasmuch as most serum enzymes are not filtered by the glomerulus because of their large molecular weight, enzymuria may be an indication of renal tubular leakage or necrosis. Several enzymes originate from specific cellular organelles and thus can serve as markers for damage to a specific site. For example, y-Glutamyl transpeptidase (GGT) originates from the proximal tubular brush border and N-acetyl glucosaminidase (NAG) is a lysosomal enzyme. Enzymuria usually precedes azotemia and decreased urine-concentrating ability associated with nephrotoxic proximal tubular injury by several days. The urine GGT: creatinine and NAG: creatinine ratios have been shown to accurately reflect 24-hour urine GGT and NAG excretion in dogs, if determined before the onset of azotemia. Baseline urine GGT:creatinine and NAG: creatinine ratios therefore should be determined in all dogs that are to receive potentially nephrotoxic drugs. Twofold to threefold increases in the GGT/creatinine or NAG/creatinine ratio over the baseline are suggestive of clinically relevant tubular damage. Drug therapy should be discontinued if this occurs.

#### **Treatment**

The goals of treatment of established ARF are to eliminate renal hemodynamic disorders and alleviate water and solute imbalances to give the nephrons additional time to repair and hypertrophy. A positive response to therapy is indicated by a decrease in the serum creatinine concentration and an increase in urine production. Induction of diuresis facilitates the management of ARF by decreasing serum urea nitrogen, phosphorus, and potassium concentrations and by lessening the likelihood of overhydration. Even though the GFR and renal blood flow may improve in response to diuresis, they are frequently unchanged, and the increased urine production is actually a result of decreased tubular resorption of filtrate (Table 44-1). Increased urine production alone does not indicate an improvement in GFR.

**TABLE 44-1** 

Hypothetical Comparison of the Glomerular Filtration Rate and Urine Production in Normal and Nonoliguric Acute Renal Failure States\*

NORMAL	ACUTE RENAL (L/DAY)	FAILURE (L/DAY)
Glomerular filtration rate	100	10
Tubular resorption	99	07
Urine production	1	03

<sup>\*</sup> These show the effect of tubular resorption on urine production in the face of decreased glomerular filtration.

Treatment guidelines for ARF are listed in Box 44-5. Most dogs and cats with ARF are dehydrated because of gastrointestinal fluid loss (e.g., vomiting) superimposed on their inability to concentrate urine. Replacement of these volume deficits will correct the prerenal component of the ARF and help protect against any additional ischemic renal tubular damage. Once the patient is rehydrated, establishing or augmenting diuresis can facilitate excretion of solutes that are reabsorbed and secreted by renal tubular cells (e.g., urca nitrogen and potassium). Increasing tubular flow rates and volumes will hinder reabsorption and favor secretion of solutes.

The large volume of fluid and rapid administration rate necessary in patients with ARF require that fluids be given intravenously. Jugular catheters or other central venous lines are ideal because they facilitate frequent blood sampling and infusion of hypertonic solutions (e.g., mannitol) and allow access for central venous pressure (CVP) measurement. Deficit fluid requirements should be replaced over the first 4 to 6 hours of treatment unless the patient has a cardiac disorder that requires a slower administration rate. A fluid bolus challenge of 20 ml/kg body weight given intravenously over 10 minutes can help assess the possibility of a subsequent volume overload. The CVP should not increase by more than 2 cm of water if the patient's cardiovascular function is normal. Because measurement of CVP is not always accurate or reproducible, results should always be interpreted in light of other parameters (e.g., patient's body weight, hematocrit, plasma total solids, and physical examination findings). The purpose of replacing volume deficits over the first 4 to 6 hours rather than over the normal 12 to 24 hours is to rapidly improve renal perfusion and decrease the likelihood of continued ischemic damage. Normal saline (0.9% solution) is the fluid of choice for rehydration unless the patient is hypernatremic, in which case a 0.45% saline with 2.5% dextrose solution should be used. The amount of fluid required to restore extracellular fluid deficits can be calculated by multiplying the estimated percentage of dehydration by the patient's body weight in kilograms.

During this rapid rehydration phase the patient should be closely observed for signs of overhydration. Frequent

BOX 44-5

#### Treatment Guidelines for Dogs and Cats with Acute Renal Failure

Discontinue all potentially nephrotoxic drugs; consider measures to decrease absorption (e.g., induction of emesis and administration of activated charcoal and sodium sulfate).

Start specific antidotal therapy if applicable (e.g., alcohol dehydrogenase inhibitors for ethylene glycol).

Identify and treat any prerenal or postrenal abnormalities. Start intravenous fluid therapy with normal saline solution

- or 0.45% saline solution in 2.5% dextrose:
- a. Rehydrate animal within 6 hours.
- Provide maintenance fluid and replace continuing fluid losses.

Assess volume of urine production.

Correct acid-base and electrolyte abnormalities; rule out hypercalcemic nephropathy.

If necessary, to increase urine production, provide mild volume expansion while monitoring urine volume, body weight, plasma total solids, hematocrit, and central venous pressure.

Administer diuretics, if necessary, to increase urine production:

- a. Mannitol or
- b. Furosemide

Base subsequent fluid volumes on urine production plus 20 ml/kg/24 h.

Consider peritoneal dialysis if there is no response to above treatment; biopsy kidney at time of dialysis catheter placement.

Control hyperphosphatemia:

- a. Phosphate-restricted diet and, if necessary,
- b. Enteric phosphate binders

Treat vomiting and gastroenteritis with:

- a. Metoclopramide,
- b. Trimethobenzamide, or
- c. Chlorpromazine

Treat gastric hyperacidity with H<sub>2</sub> blockers.

Provide caloric requirements (70 to 100 kcal/kg/day).

assessment of body weight, CVP, packed cell volume, and plasma total solids will help detect early overhydration. An increase in the CVP of  $\geq 5$  to 7 cm of water over baseline values suggests the likelihood of overhydration. Physical manifestations of overhydration include increased bronchovesicular sounds or overt crackles and wheezes, tachycardia, restlessness, chemosis, and scrous nasal discharge; however, these signs tend to be observed after the development of pulmonary edema. Overhydration in dogs and cats with oligoanuric ARF is a common complication that is extremely difficult to correct.

Urine production should be measured and electrolyte and acid-base status assessed during the period of rehydration. Urine production (ml/kg/hour) should be measured so that maintenance fluid needs can be accurately administered.

**TABLE 44-2** 

Hypothetical Examples of Daily Maintenance Fluid Requirements in Dogs and Cats

	NORMAL URINE PRODUCTION	OLIGURIC ARF	NONOLIGURIC ARF
Insensible	20	20	20
loss (ml/kg) Urine volume (ml/kg)	40	10	160
Total (ml/kg)	60	30	180

ARF, Acute renal failure.

Because approximately two thirds of normal maintenance fluid needs are due to fluid loss in urine, oliguric and nonoliguric patients can have large variations in their maintenance fluid needs (see Table 44-2). Metabolism cages, urinary catheters, and manual collection of voided urine are methods used to collect and measure urine volume. With regard to indwelling urinary catheters, strict aseptic technique and closed collection systems must be used. Because of the possibility of urinary tract infection, intermittent urinary bladder catheterization is usually recommended over indwelling catheterization for timed urine volume collections. In cats weighing the litter pan before and after voiding is a useful, although less accurate, method for assessing urine production. If an indwelling urinary catheter or a metabolism cage is not available, patients should be weighed in the same scale two or three times a day to assess fluid gain or

Initially, most patients with ARF have normal scrum sodium and chloride concentrations on account of isonatremic fluid loss. However, hypernatremia can develop after several days of therapy with fluids containing large amounts of sodium (0.9% NaCl, lactated Ringer's solution, and Normosol) and/or in association with sodium bicarbonate treatment of metabolic acidosis. If hypernatremia occurs, the use 0.45% NaCl with 2.5% dextrose fluids will usually correct the problem.

Disorders of calcium balance can also occasionally occur in patients with ARF. If moderate to severe hypercalcemia is observed, a primary hypercalcemic disorder (e.g., neoplasia or vitamin D<sub>3</sub> intoxication) should be considered as the cause of the renal failure. In most cases assessment of the ionized calcium concentration is preferable to measurement of the total calcium concentration. Immediate treatment for hypercalcemia includes rehydration with 0.9% NaCl followed by diuresis induced with furosemide. Glucocorticoids will also help lower calcium concentrations by decreasing intestinal absorption and facilitating excretion, but their use may interfere with the diagnosis of the underlying disorder (e.g., lymphoma). Intravenous bisphosphonates (pamidronate-Aredia, 1 mg/kg as a constant rate infusion (CRI) in

0.9% saline solution) are effective in lowering serum calcium concentration and do not affect the clinician's ability to diagnose the primary cause of hypercalcemia. Conversely, significant hypocalcemia can be observed in dogs and cats with ARF associated with ethylene glycol intoxication.

Oliguric ARF patients are at risk for hyperkalemia. Serum potassium concentrations greater than 6.5 to 7.0 mEq/L can cause cardiac conduction disturbances (bradycardia, atrial standstill, idioventricular rhythms, ventricular tachycardia, ventricular fibrillation, asystole) and electrocardiographic changes (peaked T waves, prolonged PR intervals, widened QRS complexes, or the loss of P waves). Mild to moderate hyperkalemia typically resolves with administration of potassium-free fluids (dilution) and improved urine flow (increased excretion). More severe hyperkalemia (>7-8 mEq/ L) or hyperkalemia resulting in electrocardiographic (ECG) abnormalities should be treated with agents that rapidly decrease serum potassium concentrations or counteract the effects of hyperkalemia on cardiac conduction. Sodium bicarbonate (see discussion of dosage later in this chapter) helps correct metabolic acidosis and lower serum potassium concentration by exchanging intracellular hydrogen ions for potassium. Insulin can also be used to increase intracellular shifting of potassium. Regular insulin is administered intravenously at a dosage of 0.1 to 0.25 U/kg, followed by a glucose bolus of 1 to 2 g per unit of insulin given. Blood glucose monitoring should be maintained for several hours after administration of insulin because hypoglycemia may occur. Ten percent calcium gluconate (0.5-1.0 ml/kg administered intravenously over 10 to 15 minutes) will counteract the cardiotoxic effects of hyperkalemia without lowering the serum potassium and can be used in emergency situations. The effects of the aforementioned regimens are short-lived, and fluid and acid-base therapy to initiate and maintain a diuresis and maintain blood pH and bicarbonate within the normal range (discussed in more detail later in this chapter) are important to maintain potassium excretion and normokalemia.

Mild to moderate metabolic acidosis also generally resolves after fluid therapy, and specific treatment is usually not necessary unless the blood pH is less than 7.2 or the total  $CO_2/CO_3H$  is less than 12 mEq/L. Bicarbonate requirements can be calculated using the base deficit as determined from arterial blood gas, or an estimated base deficit [body weight (kg)  $\times$  0.3  $\times$  base deficit or  $(20-T\ CO_2)$  = mEq bicarbonate required]. Optimally, one half the calculated bicarbonate dosage should be administered intravenously over 15 to 30 minutes, and then acid-base parameters reassessed. Overzealous bicarbonate administration may result in ionized hypocalcemia, paradoxical cerebral spinal fluid (CSF) acidosis, and/or cerebral edema.

If signs of overhydration are not present and oliguria persists after apparent rehydration, mild volume expansion (3% to 5% of the patient's body weight in fluid) may be initiated inasmuch as dehydration of this magnitude is difficult to detect clinically. If volume expansion is attempted, the possibility of inducing overhydration increases and close

patient observation is necessary. Unfortunately, most patients that have oliguria will remain oliguric after rehydration and volume expansion.

In the past, diuretic therapy was frequently recommended in patients that were persistently oligoanuric despite appropriate fluid therapy. Compared with those patients with diminished urine production, polyuric ARF patients are thought to have less severe tubular injury, improved excretion of solutes that are reabsorbed or secreted (e.g., urea nitrogen and potassium), and less risk of developing overhydration and pulmonary edema. There is, however, no evidence that diuretic therapy will hasten the recovery from ARF or decrease mortality associated with ARF. In humans with established ARF, there is increasing evidence that diuretic therapy may actually be associated with increased risk of death and nonrecovery of renal function. If the choice is to use diuretics in dogs or cats with ARF, they should be used only after dehydration has been corrected and the patient has been volume expanded. Furosemide and mannitol are probably the diuretics of choice. Dopamine is not recommended because of its unpredictable effects on renal blood flow and GFR.

Furosemide blocks the reabsorption of chloride and sodium in the thick ascending limb of Henle, resulting in natriuresis and osmotic diuresis. The dose recommended for oligoanuric dogs and cats is 2 to 6 mg/kg IV q8h; however, in healthy dogs CRI of furosemide with a 0.66 mg/kg IV loading dose followed by 0.66 mg/kg/h resulted in more diuresis, natriuresis, and calciuresis and less kaliuresis than did intermittent bolus infusion.

Mannitol, in a 10% or 20% solution, has been recommended as an osmotic diuretic at a dose of 0.5 to 1.0 g/kg, given intravenously as a slow bolus over 15 to 20 minutes. Urine output should increase within 1 hour if the treatment is effective. A second bolus may be attempted, but the potential for volume overexpansion and complications such as pulmonary edema increases considerably if urine production does not increase. As an osmotic agent, mannitol may decrease tubular cell swelling, increase tubular flow, and help prevent tubular obstruction or collapse. In healthy cats the renal effects of mannitol, when used as an adjunct to fluid therapy, are superior to those of furosemide and dopamine combination. The use of mannitol is contraindicated in an overhydrated patient because the resultant increase in intravascular volume may precipitate pulmonary edema.

Whether or not diuresis can be established, fluid therapy should be tailored to match urine volume and other losses, including insensible losses (e.g., water loss caused by respiration) and continuing losses (e.g., fluid loss caused by vomiting or diarrhea). Insensible losses are estimated at 20 ml/kg/day. Urine output is quantitated for 6- to 8-hour intervals, and that amount is replaced over an equivalent subsequent time period. The volume of fluid loss resulting from vomiting and/or diarrhea is estimated, and that amount is added to the 24-hour fluid needs of the patient. Fluid losses or gains can also be indirectly estimated by weighing the patient 2 to

3 times a day on the same scale. If hypernatremia and hyperkalemia are not present and a diuresis has been established, polyionic maintenance fluids (e.g., lactated Ringer's solution, Normosol) should be used. In the recovery phase of ARF, urine volume and electrolyte losses can be great. Potassium supplementation may be necessary, especially if the patient is vomiting or anorectic.

Control of nausea and vomiting in dogs and cats with ARF is important to facilitate caloric intake. In addition, the inability to control vomiting is discouraging to owners and may result in a hastened decision for cuthanasia. (Please see the section on management of chronic kidney disease for specific recommendations for the treatment of nausea and vomiting.)

When fluid therapy is successful in inducing or maintaining diuresis, the daily volume of fluid administered to the patient will eventually need to be decreased. Indications for tapering IV fluid volume include the following: (1) significant decreases in BUN and phosphorus concentrations, (2) control of vomiting and diarrhea, and (3) improved mood and renewed interest in eating and drinking. These indications rarely occur before 5 or 6 days of intense fluid therapy/ diuresis and may require 10 or more days of treatment. Gradually reducing maintenance fluid requirements by 25% each day is usually recommended for fluid tapering. If the patient loses weight or increases in packed cell volume, total protein, and BUN and/or creatinine concentrations are observed, fluid therapy tapering should be discontinued and the previous maintenance volume reinstated for at least 48 hours.

Peritoneal or hemodialysis should be considered in patients with severe, persistent uremia, acidosis, or hyperkalemia. Dialysis may also be used to treat overhydration and hasten elimination of dialyzable toxicants. Renal biopsy should be performed if the diagnosis is in doubt, if the patient does not respond to therapy within 3 to 5 days, or if dialysis is considered. The long-term prognosis for dogs or cats with ARF is usually fair to good if the patient survives the period of renal tubular regeneration and compensation; however, several weeks may be required for renal function to improve. Animals with moderate to severe renal damage may require many weeks for renal repair, and the prolonged time required for recovery results in a poor prognosis. The severity of the initial azotemia/uremia, the response to fluid therapy, and assessment of renal histopathologic lesions are the most important prognostic indicators early in the course of ARF.

# CHRONIC KIDNEY DISEASE

## **Etiology and Pathogenesis**

Unlike ARF, the cause of CKD is usually difficult to determine. Because of the interdependence of the vascular and tubular components of the nephron, the end-point of irreversible glomerular or tubular damage is the same. A morphologic heterogeneity among nephrons exists in the

chronically diseased kidney, with the changes ranging from severe atrophy and fibrous connective tissue replacement to marked hypertrophy. The histopathologic changes are not process-specific, and therefore the cause is usually unknown. Nevertheless, recent studies have shown that primary glomerular disorders are a major cause of CKD in the dog. Because glomerular filtration *in toto* is uniformly reduced, CKD may be considered a single pathologic entity, although many diverse pathways can lead to this end-point. Potential causes of CKD are listed in Box 44-6.

The pathophysiology of CKD can be considered at both the organ and systemic level. At the level of the kidney, the fundamental pathologic change that occurs is a loss of nephrons and decreased GFR. Reduced GFR, in turn, results in increased plasma concentrations of substances that are normally eliminated from the body by renal excretion. Many substances have been shown to accumulate in the plasma of patients with CKD (Box 44-7). The constellation of clinical signs known as the *uremic syndrome* is thought to occur, at least in part, as a result of increasing plasma concentrations

of these substances. Components of the uremic syndrome include sodium and water imbalance, anemia, carbohydrate intolerance, neurologic disturbances, gastrointestinal tract disturbances, osteodystrophy, immunologic incompetence, and metabolic acidosis.

In addition to excreting metabolic wastes and maintaining fluid and electrolyte balance, the kidneys also function as endocrine organs and catabolize several peptide hormones. Therefore hormonal disturbances also play a role in the pathogenesis of CKD. For example, the decreased production of erythropoietin (EPO) and calcitriol in animals with CKD contributes to the development of nonregenerative anemia and hyperparathyroidism. Conversely, decreased metabolism and increased concentrations of parathyroid hormone (PTH) and gastrin contribute to the development of hyperparathyroidism and gastritis, respectively.

Some of the pathophysiologic changes that occur in CKD are brought about by compensatory mechanisms. The osteodystrophy of CKD occurs secondary to hyperparathyroidism, which develops in an attempt to maintain normal plasma calcium and phosphorus concentrations. Similarly, the GFR of intact hypertrophied nephrons increases in animals with CKD in an attempt to maintain adequate renal function; however, proteinuria and glomerulosclerosis in these individual nephrons, leading to additional nephron damage and loss, may be consequences of this hyperfiltration (Fig. 44-3).

#### **Clinical Features and Diagnosis**

Unlike ARF, CKD develops over a period of months or years, and its clinical signs are often relatively mild for the magni-

tude of the azotemia. Unique signs of CKD include a history of weight loss, polydipsia-polyuria, poor body condition, nonregenerative anemia, and small and irregularly shaped kidneys. A diagnosis of CKD is usually based on a combination of compatible historical, physical examination, and clinicopathologic findings. Plain radiographs can confirm the presence of small kidneys. Renal ultrasonography will usually show diffusely hyperechoic renal cortices with loss of the normal corticomedullary boundary. The increased cortical echogenicity results from replacement of the irreversibly damaged nephrons with fibrous connective tissue. Radiographic studies and ultrasonography can also help identify or rule out potentially treatable causes of CKD, such as pyelonephritis and renal urolithiasis. Renal biopsy is not routinely performed in animals with CKD unless the diagnosis is in question. Renal histopathologic preparations will show some combination of a loss of tubules with replacement fibrosis and mineralization, glomerulosclerosis and glomerular atrophy, and foci of mononuclear cells (small lymphocytes, plasma cells, and macrophages) within the interstitium in association with fibrous connective tissue replacement.

**FIG 44-3**Proposed pathogenesis of progressive loss of nephrons in chronic kidney disease.

# STAGING CHRONIC KIDNEY DISEASE

Once a diagnosis of CKD has been established and fluid therapy has resolved any prerenal azotemia, staging the disease process can help clinicians focus their diagnostic and therapeutic efforts. The International Renal Interest Society (IRIS) was created to advance the scientific understanding of kidney diseases in small animals at the Eighth Annual Congress of the European Society of Veterinary Internal Medicine in Vienna, Austria in 1998. Seventeen independent veterinary nephrologists from eight countries serve on the IRIS Board, with the mission of helping practitioners better diagnose, understand, and treat canine and feline renal disease. Table 44-3 was developed by the IRIS Board as guide to staging canine and feline CKD.

Scrum creatinine concentrations must always be interpreted in light of the patient's urine specific gravity and physical examination findings to rule out prerenal and postrenal causes of azotemia. The CKD stages are further classified by the presence or absence of proteinuria and systemic hypertension (Table 44-4).

The classic diagnosis of renal failure based on renal azotemia (persistent azotemia superimposed on the inability to

concentrate urine) pertains to CKD stages II through IV. Stage I CKD (nonazotemic CKD) could be diagnosed in cats and dogs with persistent proteinuria, urine-concentrating deficits, increases in serum creatinine concentration over time even if the values remain in the normal range (e.g., serum creatinine concentration that increases form 0.6 to 1.2 mg/dl could indicate a 50% reduction in GFR), or abnormal renal palpation or renal ultrasonographic findings.

# **Further Diagnostics and Treatment**

In general, the diagnostic approach to a patient in which CKD has been identified and staged is focused on three areas: (1) characterization of the renal disease, (2) characterization of the stability of the renal disease and renal function, and (3) characterization of the patient's problems associated with the decreased renal function (Fig. 44-4). Further definition of the renal disease (beyond a standard minimum database) could include, for example, quantification of proteinuria, measurement of blood pressure, urine culture, kidney imaging, and possibly kidney biopsy. The stability of the renal function may be assessed by serial monitoring of abnormalities identified during the initial evaluation of the renal disease. This monitoring should always include serial serum biochemistry profiles, urinalyses, quantification of proteinuria, and measurement of blood pressure, but it may also include follow-up urine cultures and ultrasonographic examinations. Characterization of the renal disease and its stability is most important in the earlier stages of CKD, when appropriate treatment has the greatest potential to improve or stabilize renal function. Characterization of the patient's problems becomes more important in the later stages of CKD, when clinical signs tend to be more severe. In the later stages of CKD, diagnostic (and subsequent therapeutic) efforts should be directed at the anorexia, vomiting, acidosis, potassium depletion, hypertension, anemia, and related signs.

Similar to the diagnostic approach to CKD, the therapeutic approach should also be tailored to fit the patient's stage of disease. For example, disease-specific treatments for neph-

roliths or bacterial pyelonephritis as well as treatments designed to slow the progression of renal disease (so-called renoprotective treatments) will be of most value in the earlier stages of CKD. Examples of renoprotective treatments include dietary change designed to reduce serum phosphorus concentrations and ACEIs designed to normalize systemic and intraglomerular blood pressures and reduce proteinuria. In the later stages of CKD, treatment tends to be focused on ameliorating the patient's clinical signs associated with the decreased renal function.

Specific treatment in patients with CKD is directed at the primary cause of the kidney disease. Although it may not be possible to identify the primary cause of the CKD, specific treatment have the potential to reduce the magnitude of subsequent renal damage. As an example, bacterial pyelonephritis can cause or complicate CKD, and the condition can be specifically treated with appropriate antibiotic therapy. The prevalence of urinary tract infection (UTI) increases in older dogs and cats, and especially dogs and cats with CKD, because the antibacterial properties of the urine decline as its concentration decreases. In a study of cats with naturally occurring CKD, 29% had occult UTI. Bacterial infection of the renal pelvis and parenchyma (i.e., pyelonephritis) can then result from an ascending lower UTI. Initially with ascending UTI, the renal cortex is not affected; however, as chronic pyelonephritis develops, the entire kidney may become involved. Pyclonephritis also can precipitate the development of renal calculi, and, conversely, renal calculi can increase the risk of pyelonephritis. Long-term antibiotic therapy based on culture and sensitivity may halt the renal damage associated with pyelonephritis; however, if renoliths are present, antibiotic therapy alone is usually ineffective. Calcium oxalate uroliths are the most common type of renoliths in older cats, and because they cannot be dissolved, surgery is necessary for stone removal. Anesthesia and surgery, however, have the potential to further compromise renal function in the cat with CKD. In most cases, the patient is closely monitored for obstructive uropathy and surgery

is not performed unless an obstruction develops. Concurrent pyelonephritis that cannot be resolved with antibiotic treatment is another potential indication for surgical intervention.

Similar to bacterial pyelonephritis, hypertension (HT) can cause or complicate CKD. Gradual reduction of dietary salt intake is often recommended as the first line of treatment for HT; however, no studies document the efficacy of dietary salt reduction in lowering blood pressure in dogs or cats. In many cases vasodilators (ACEI and calcium channel blockers [CCBs]) may be necessary to control hypertension. Although ACEIs are usually recommended for HT associated with CKD in dogs, amlodipine is often recommended as the first-choice antihypertensive medication for cats. Recent studies, however, have raised the concern that amlodipine as a monotherapy in animals with renal disease may expose the glomeruli to higher pressures because of efferent arteriolar constriction caused by local increases in renin-angiotensinaldosterone system activity. If so, cats with renal disease should benefit from therapy with both ACEIs and CCBs. Cats with CKD are mild to moderate HT should be treated with an ACEI (e.g., benazepril: 0.5 to 1.0 mg/kg q24h) because of the positive effects on intraglomerular hypertension and proteinuria. In cats with severe HT (systolic blood pressure >180 mm Hg) or cats in which HT persists despite ACEI treatment, amlodipine (0.625 to 1.25 mg/cat q24h) treatment should be initiated. Several studies have documented renoprotective effects of ACEIs in dogs and cats with naturally occurring CKD.

Direct-acting vasodilator drugs such as ACEIs and CCBs are the most successful in achieving acute reduction of blood pressure, but sympathetic nervous system—mediated increases in heart rate and aldosterone-mediated sodium and water retention may modulate the effects of the vasodilation over time. Combining antihypertensive treatments with different modes of action may block the compensatory effects caused by one medication when used alone. For example, diuretics, aldosterone antagonists, and  $\beta$ -blockers, which may have minimal antihypertensive effect alone, may produce additive effects when given in combination with ACEIs or CCBs. Overall, the risk of target organ damage in the eyes, brain, kidneys, and heart is thought to be minimal if systolic blood pressure is <150 mm Hg (Table 44-5).

In many dogs and cats with stage II to IV CKD, renal lesions progress and renal function deteriorates (see Figure 44-1). Progressive loss of function as well as the rate of decline are monitored by longitudinal measurement of serum creatinine concentrations. In addition to the antihypertensive treatment discussed previously, ACEIs (to control intraglomerular hypertension and proteinuria) and dietary phosphorus restriction are examples of so-called renoprotective treatments. Reduction of dietary phosphorus is one of the cornerstones of management of CKD and can be accomplished by feeding specifically formulated diets for CKD. From a practical standpoint, dietary phosphorus reduction is combined with dietary protein reduction (discussed in more detail later). If, after 3to 4 weeks of dietary

**TABLE 44-5** 

Risk of Target Organ Damage Associated with Hypertension in Dogs and Cats

SYSTOLIC BLOOD PRESSURE (MM HG)	DIASTOLIC BLOOD PRESSURE (MM HG)	RISK LEVEL	
<150	<95	Minimal

≥180	≥120	High	

phosphorus reduction, serum phosphorus concentrations remain high, enteric phosphate-binding gels containing calcium acetate, calcium carbonate, or aluminum hydroxide should be administered with meals (initial dosage of 30 mg/kg body weight with the dosage increased as needed to achieve normophosphatemia).

Hyperphosphatemia in patients with CKD occurs as a result of decreased renal excretion of phosphates. Concurrently, decreased renal production of the active form of vitamin D, decreases intestinal absorption of calcium, which, in conjunction with impaired renal reabsorption of calcium, decreases plasma ionized calcium concentrations. Decreased vitamin D<sub>3</sub> and serum calcium concentrations stimulate PTH secretion, which facilitates renal excretion of phosphorus and increases serum calcium concentrations by increasing renal calcium reabsorption and calcium absorption from bones and the gastrointestinal tract. The disadvantages of this hyperparathyroidism, however, can be severe and include osteodystrophy, bone marrow suppression, and soft tissue mineralization. Soft tissue mineralization occurs predominantly in damaged tissue, and if mineralization occurs in renal tissue, the result may be a progressive decline in renal function. If the product of the serum calcium and phosphorus concentrations is greater than 50 to 70 mg/dl, the patient is at risk for soft tissue mineralization. Studies in dogs and cats with remnant kidney CKD have shown that normal dietary phosphorus intake is associated with microscopic renal mineralization and fibrosis, and these changes were prevented by reducing dietary phosphorus. Similarly, in dogs and cats with naturally occurring CKD, feeding a diet specifically formulated to meet their needs, together with phosphate-binding drugs, if required, controls hyperphosphatemia and secondary renal hyperparathyroidism and is associated with a prolonged survival time. Physiologic doses of calcitriol may also be beneficial in dogs and cats with hyperparathyroidism and hyperphosphatemia associated with CKD. In a prospective, randomized, controlled clinical trial in dogs with spontaneous CKD (stages III and IV), calcitriol treatment (initial dose of 2.5 ng/kg/day that was adjusted within the range of 0.75 to 5.0 ng/kg/day according to serial determination of ionized calcium and PTH concentrations) resulted in decreased all-cause mortality and prolonged survival compared with placebo treatment. Calcitriol should not be administered until hyperphosphatemia has been controlled with diet and enteric binders. In addition, if the Ca X Phos product exceeds 60 to 70 mg/dl, calcitriol should not be used because of the risk of soft tissue mineralization. Serial serum calcium determinations are recommended in dogs and cats receiving calcitriol to help prevent hypercalcemia, especially if the patient is also receiving a calcium-containing enteric phosphorus binder.

Diagnosis and management of proteinuria in dogs and cats with CKD should be accomplished in a step-wise fashion. Because the specificity of the dipstick screening test for proteinuria in both dogs and cats is poor, confirmation of proteinuria should be accomplished with a more specific follow-up test, such as the sulfosalicylic acid (SSA) turbidimetric test, urine protein: creatinine ratio, or canine or feline specific albuminuria assay (see Chapter 42). The second step in assessment of proteinuria is to determine its origin. Proteinuria of renal origin can adversely affect the prognosis of dogs and cats with CKD, and therefore physiologic or benign proteinuria and prerenal and postrenal proteinuria should be ruled out. Subsequently, via serial monitoring, the clinician should determine whether the proteinuria is persistent or transient. Persistent proteinuria is defined as at least two positive tests at 2-week intervals. Relatively mild proteinuria in dogs and cats with spontaneous chronic renal failure appears to be a negative predictor of survival. In azotemic patients persistent proteinuria of renal origin with a urine protein: creatinine ratio > 0.4 (cats) or > 0.5 (dogs) should be treated with an ACEI and/or dietary protein reduction (discussed in more detail later).

Symptomatic treatment becomes a higher priority in the later stages of CKD, when the renal failure and uremia have a more pronounced effect on the patient's quality of life. In addition to phosphorus restriction, dietary management includes protein reduction (dietary protein is reduced not restricted in these diets; restriction of any dietary component generally means feeding less than the daily requirements), salt reduction, n-3 fatty acid supplementation, and alkalinization. Feeding specifically formulated renal failure diets not only may allow the animal to live more comfortably with decreased renal function but also may significantly prolong survival. Ideally, dietary protein reduction allows all essential amino acid requirements to be met without excesses. This is accomplished by feeding smaller quantities of high biological value protein and results in a decreased need for renal clearance of urea and other nitrogenous metabolites. When feeding reduced protein diets, the clinician must remember that the energy requirements of the body have a higher priority than does protein anabolism; therefore, if the available carbohydrates and fats are insufficient to meet caloric requirements, endogenous proteins will often be used as a source of energy. Catabolism of endogenous proteins for energy increases the nitrogenous waste that the kidney must excrete and exacerbates the clinical signs of renal failure.

A good recommendation for dietary protein reduction for both dogs and cats is to feed the maximum amount of high biological value, highly digestible protein that the animal can tolerate at his/her level of renal function. A favorable response to therapy consists of stable body weight and serum creatinine and albumin concentrations and decreasing serum urea nitrogen and phosphorus concentrations. Moderate dietary protein reduction should be employed early in the course of renal failure, and use of markedly reduced protein diets should be reserved for patients that are refractory to moderate dietary protein reduction.

Most diets for CKD are alkalinizing diets; however, potassium citrate or sodium bicarbonate, given orally to effect, may be indicated if the patient remains acidemic (total CO<sub>2</sub> < 12 mEq/L) 2 to 3 weeks after diet change. Oral potassium citrate supplementation may also prevent hypokalemia and potassium depletion in cats with CKD. Anorexia; highprotein, acidifying diets; polyuria-polydipsia; and vomiting can all contribute to potassium depletion; however, only 20% to 30% of cats with CKD have hypokalemia as an initial clinicopathologic finding. Potassium is predominantly an intracellular cation, and approximately 95% of total body potassium is present in skeletal muscle; therefore serum potassium concentrations may not accurately reflect total body potassium stores, especially in the early stages of potassium depletion. It has been documented that cats with CKD have lower muscle potassium concentrations and higher serum potassium concentrations than do normal cats. This data may suggest the need for oral potassium supplementation early in the course of CKD in cats. Generalized muscle weakness is the primary clinical sign associated with hypokalemia/potassium depletion. Muscle weakness usually resolves within 1 to 5 days after initiation of oral potassium supplementation.

Vomiting and anorexia are common in dogs and cats with CKD and can often result in decreased caloric intake. Causes of vomiting and anorexia include (1) stimulation of chemoreceptor trigger zone by uremic toxins, (2) decreased excretion of gastrin and increased gastric acid secretion (plasma gastrin concentrations in cats with chronic renal failure may be as high as 20 times the normal concentrations), and (3) gastrointestinal irritation secondary to uremia. Vomiting may be treated with metoclopramide, which blocks the chemoreceptor trigger zone. Metoclopramide also increases gastric motility and emptying without causing gastric acid secretion and is the drug of choice for vomiting associated with renal failure. H2 receptor blockers (famotidine or ranitidine) have been shown to effectively decrease gastric acid secretion, which may attenuate vomiting in CKD. Oral ulcers, stomatitis, and glossitis may occur as a result of gastritis and vomiting or the effect of uremic toxins on mucosal membranes and will often also result in anorexia. If vomiting has been controlled but anorexia persists, placement of a gastrostomy or esophagostomy tube will often facilitate the maintenance of caloric intake and hydration status. In many cases without feeding tubes, fluid therapy with polyionic solutions, given intravenously or subcutaneously in the hospital or subcutaneously by owners at home (10 to 50 ml/kg subcutaneously every 1 to 3 days), will help improve the patient's quality of life.

The nonregenerative anemia observed in dogs and cats with CKD occurs as a result of a combination of decreased EPO production, shortened red blood cell survival, gastrointestinal tract blood loss, and the effects of uremic toxins such as PTH on erythropoiesis. In addition, nutritional deficiencies (e.g., vitamins B<sub>6</sub> and B<sub>12</sub>, niacin, and folic acid) and iron depletion can contribute to the anemia associated with CKD. Anabolic steroids are usually of little benefit; however, treatment with recombinant human EPO in dogs and cats with CKD and anemia has generally been successful. Although not approved for use in veterinary medicine, the dosage that has been recommended is 100 U/kg of recombinant EPO given subcutaneously three times weekly. The dose interval is lengthened once a target packed cell volume is achieved (approximately 40% in dogs and 35% in cats). Usually, a dosage of 75 to 100 U/kg once or twice weekly is sufficient for maintenance. This treatment, in addition to increasing the packed cell volume, often results in increased appetite, weight gain, increased strength, and an improved sense of well-being. It should be noted, however, that antibodies may form in dogs and cats treated with human recombinant products. Studies show that antirecombinant EPO-binding antibodies will develop in approximately 25% to 30% of dogs and cats and that these antibodies may also react with endogenous EPO, making the animal transfusion dependent. Development of anti-r-HuEPO antibodies should be suspected in patients with a sudden decrease in packed cell volume. Iron deficiency; external blood loss; hemolytic disorders; and concurrent infectious, inflammatory, or neoplastic diseases should be ruled out in such patients. The absence of peripheral reticulocytes and severe erythroid hypoplasia (M:E ratio >10) on bone marrow cytology is compatible with the presence of anti-r-HuEPO antibodies. Iron supplementation (iron dextran: 10 mg/kg administered intramuscularly every 3 to 4 weeks) should be employed during recombinant EPO treatment because of the rapid initiation of erythropoiesis and marginal depletion of iron stores that occur in animals with CKD. Until canine and feline recombinant EPO become commercially available, treatment with human recombinant products should be reserved for those animals with weakness and lethargy attributable to their anemia.

# CHAPTER A Urinary Tract Infections

### CHAPTER OUTLINE

### URINARY TRACT INFECTIONS

Etiology and Pathogenesis
Host Defense Mechanisms
Complicated Versus Uncomplicated Urinary Tract
Infections
Relapses Versus Reinfections
Clinical Features
Treatment

### URINARY TRACT INFECTIONS

Bacterial infections of the urinary tract occur more frequently in dogs than in cats. Although inflammatory disease of the lower urinary tract is common in cats, bacterial infections are rare. Fewer than 2% of the cases of lower urinary tract disease (LUTD) in cats are caused by a primary urinary tract infection (UTI). Most of the UTIs in dogs involve bacterial inflammation of the lower urinary tract (bladder, urethra); however, the ascension of bacteria into the ureters and kidneys is a potential sequela of lower UTIs. Compared with the prevalence of bacterial UTIs, mycoplasmal, chlamydial, viral, and fungal UTIs are rare in dogs. Most bacterial infections of the lower urinary tract respond quickly to appropriate antibiotic treatment; however, UTIs associated with defects in the host immune system (complicated UTIs) often fail to respond to antibiotic therapy, or the infection relapses shortly after antibiotic withdrawal.

### **Etiology and Pathogenesis**

The most common bacterial pathogens associated with UTIs in the dog include Escherichia coli, Staphylococcus, Streptococcus, Enterococcus, Enterobacter, Proteus, Klebsiella, and Pseudomonas organisms. E. coli is the most common isolate from canine and feline urine (Table 45-1). Although UTIs usually involve a single organism, as many as 20% to 30% may be mixed bacterial infections (i.e., two or more species). Most bacterial UTIs are thought to be caused by intestinal or cuta-

neous flora that ascend through the urethra to the bladder. Although many enteric organisms are anaerobes, the oxygen tension in urine probably inhibits the growth of strict anaerobic bacteria; therefore anaerobes rarely cause UTIs.

Bacterial virulence of invading organisms is a major factor that determines whether a UTI becomes established (Box 45-1). The ability of bacteria to adhere to the epithelial surface of the urinary tract prevents bacterial washout during voiding and allows bacteria to proliferate between urine voidings. Infection of the urinary tract usually involves bacterial colonization of the genitalia, migration of the bacteria along the urethra, and adherence of the organisms to the uroepithelium. Uroepithelial adherence is facilitated by fimbriae, which are rigid, filamentous, proteinaceous appendages found on many gram-negative bacteria. Other factors that increase bacterial virulence include capsular K antigens, which interfere with opsonization and phagocytosis, and O antigens in endotoxin, which decrease smooth muscle contractility. The latter may stop ureteral peristalsis and facilitate the ascension of bacteria from the bladder to the kidney. E. coli isolates from dogs have a greater ability to produce colicins (resulting in increased vascular permeability), hemolysins (increasing their invasiveness through tissue damage), and [-lactamase (causing resistance to ]-lactam antibiotics) and to ferment dulcitol (which is associated with resistance to phagocytosis), but they have a decreased ability to agglutinate red blood cells (RBCs; associated with uroepithelial adherence) compared with human E. coli isolates. Finally, cell wall-deficient bacterial variants may thrive in hypertonic environments such as the renal medulla and urine, where white blood cell (WBC) migration and phagocytosis may be compromised.

Bacterial resistance to antimicrobial drugs may result from inherent resistance, from mutation and selection, or from the transfer of resistance factors (R factors) between organisms through DNA transfer. An entire bacterial population can acquire resistance by genetic transfer after only one dose of an antibiotic. The R factor phenomenon has been identified in gram-negative bacteria, including *E. coli, Enterobacter, Klebsiella*, and *Proteus*. R factor resistance to multiple drugs is common, and R factors are known to

**TABLE 45-1** 

Approximate Percentages of Bacterial Isolates in Dogs with Urinary Tract Infections

ISOLATES	PERCENTAGE OF TOTAL		
E. coli	45		
Staphylococcus spp.	13		
Proteus spp.	10		
Enterococcus	8		
Klebsiella spp.	7		
Streptococcus spp.	6		
Enterobacter spp.	3		
Pseudomonas spp.	3		
Other organisms	5		

BOX 45-1

### Factors Affecting Bacterial Virulence

Fimbriae—facilitate attachment to uroepithelium Capsular K antigens—increase invasiveness and interfere with opsonization and phagocytosis

O antigens in endotoxin—decrease smooth muscle contractility

Cell wall-deficient bacterial variants—can exist in hypertonic environments (urine, renal medulla) where host defense mechanisms may be compromised

Colicins-increase vascular permeability

Hemolysins—increase invasiveness through tissue damage β-Lactamase—causes resistance to β-lactam antibiotics Dulcital fermentation—causes resistance to phagocytosis Erythrocyte agglutination—associated with uroepithelial

adherence

Drug resistance

Inherent resistance

Mutation and selection Resistance factor transfer

confer resistance to penicillins, cephalosporins, aminoglycosides, tetracyclines, chloramphenicol, sulfonamides, and trimethoprim.

Mycoplasmal organisms have also been associated with UTIs in dogs, but this type of infection is uncommon. Clinical signs of mycoplasmal cystitis may include hematuria, pollakiuria, stranguria, incontinence, polydipsia-polyuria, and fever; however, some dogs with positive urine culture results are asymptomatic. Whether mycoplasmas are primary urinary tract pathogens remains unclear.

### **HOST DEFENSE MECHANISMS**

The status of the host defense mechanisms appears to be the most important factor influencing the pathogenesis of UTI (Table 45-2). Normal voiding is an efficient natural defense

**TABLE 45-2** 

Host Defense Mechanisms and Abnormalities that May Lead to Complicated Urinary Tract Infections

HOST DEFENSES	ABNORMALITIES	
Normal Micturition		
Normal urine volume Normal voiding frequency Small residual urine volume	Urinary incontinence Urine outflow tract obstruction Incomplete bladder emptying	
Anatomic Structures		
Urethral high-pressure zone Urethral contraction and peristalsis Urethral length Vesicoureteral valvelike junction Ureteral contractions and peristalsis	Urethral anomalies Urethrostomy surgery Ectopic ureter Urachal diverticula Vesicoureteral reflux Indwelling urinary catheter Urinary incontinence Vaginal stricture Ureteral dilatation or hydroureter	
Mucosal Defense Barriers		
Antibody and muco- protein production Nonpathogenic flora colonization	Mucosal trauma Urolithiasis Catheterization Immunoglobulin A deficiency Neoplasia Cyclophosphamide-induced damage

Humoral immunity	Hyperadrenocorticism Diabetes melitus Chronic kidney disease Neoplasia	

mechanism against UTI. The mechanical washout that occurs as a result of complete voiding is responsible for removing more than 95% of nonadherent bacteria that gain entrance into the urinary bladder. Washout is enhanced by increased urine production and frequency of voiding. Disorders that decrease the frequency of voiding or the volume of voided urine or that result in an increased urine residual volume may predispose animals to the development of UTIs. The normal urine residual volume for dogs and cats is less than 0.2 to 0.4 ml/kg.

Bacteria are normally present in increasing numbers from the midurethra to the distal urethra, but these organisms seldom cause UTIs in normal dogs. The high-pressure zone in the midurethra and the spontaneous urethral contractions help prevent the ascension of bacteria. Differences in epithelial morphology (decreased epithelial receptor sites) also help decrease the number of bacteria that can colonize the proximal and middle sections of the urethra. The length of the urethra and zinc-containing bacteriostatic/bactericidal prostatic secretions contribute to a lower incidence of UTIs in male dogs than in female dogs. In both genders the valvelike nature of the vesicoureteral junction confers protection against the ascension of bacteria to the kidneys.

The colonization of vulval and preputial luminal mucous membranes by nonpathogenic flora also serves to decrease colonization by uropathogens. Normal flora occupy most of the epithelial receptor sites, produce bacteriocins that interfere with uropathogen metabolism, and have a high affinity but low requirement for the essential nutrients needed by uropathogens. In addition, mucosal secretions help prevent the adherence of uropathogens to the epithelium; specifically, secretory immunoglobulins do so by coating pathogenic bacteria, and glycosaminoglycans by forming a protective barrier over the epithelial surface.

The antibacterial properties of urine constitute an important host defense mechanism against UTIs. Urine is frequently bacteriostatic and sometimes can be bactericidal, depending on its composition. The combination of a low pH and high concentrations of urea and weak organic acids in concentrated urine inhibits bacterial growth. The increased urine-concentrating ability of cats compared with dogs is thought to be one of the reasons that normal cats have so few bacterial UTIs. Dilute urine formed in animals with polydipsic-polyuric disorders has less antibacterial activity than hypersthenuric urine does. For example, the prevalence of bacterial UTI is higher in both dogs and cats with chronic kidney disease (CKD). Animals with CKD also often have decreased concentrations of antibiotic in their urine during treatment associated with decreased renal excretion of the drug.

# COMPLICATED VERSUS UNCOMPLICATED URINARY TRACT INFECTIONS

Uncomplicated UTIs occur in the absence of underlying structural or functional abnormalities in the host defense mechanisms. They are easier to treat than complicated UTIs and are usually cleared soon after appropriate antibiotic treatment is initiated. Complicated UTIs are associated with defects in the host defense mechanisms (i.e., interference with normal micturition, anatomic defects, damage to mucosal barriers, alterations in urine volume or composition, or systemic immunocompromise). It is usually not possible to eliminate the clinical and clinicopathologic signs of complicated UTIs with antibiotic treatment alone; signs either persist during antibiotic treatment or recur shortly after antibiotic withdrawal. Because of the relatively low prevalence of UTIs in male dogs compared with female dogs,

any UTI in a male dog should be considered a complicated infection.

Disorders of micturition are often complicated by UTI. Urine retention or incomplete voiding allows more time for bacteria to multiply within the urinary tract. Urine retention may also cause bladder wall distention that can compress intramural vessels and thereby decrease the number of WBCs and other antimicrobial factors that enter the bladder lumen. Conversely, urinary incontinence associated with decreased urethral sphincter tone may predispose the patient to an ascending UTI. Damage to mucosal barriers (e.g., transitional cell carcinoma [TCC]) may also result in the development of a complicated UTI depending on the extent of the lesion and whether uropathogens are concurrently introduced. Interestingly, bacterial inoculation of the urinary bladder in experimental animals usually fails to establish a UTI that lasts beyond 2 to 3 days, unless the uroepithelium is first damaged by a chemical or mechanical insult.

Whenever the urinary bladder is catheterized, bacteria are carried up the urethra to the bladder. If the catheter is inserted too far and damages the bladder mucosa, the chance of infection increases greatly. Anatomic defects may also allow the ascending migration of bacteria (e.g., indwelling urinary catheter, ectopic ureter) or may damage mucosal barriers (e.g., urolithiasis, neoplasia, urachal remnant, thickened bladder wall caused by chronic inflammation). In one study of 137 dogs cared for in an intensive care unit, indwelling urethral catheters were associated with UTI in 26 cases (19%); another similar study of 39 dogs demonstrated a UTI rate of 10%. Decreased urine volume may also be associated with a heightened risk for UTI because of decreased washout (although concentrated urine has greater antibacterial properties), and altered urine composition (glucosuria or the excretion of irritating substances such as cyclophosphamide metabolites that result in hematuria) can make the environment more receptive to bacterial growth. In addition to these local factors, systemic disorders, such as renal failure, hyperadrenocorticism, prolonged corticosteroid administration, neoplasia, and diabetes mellitus, can result in a complicated UTI. Potential mechanisms suggested to increase the risk of UTI in dogs with hyperadrenocorticism and/or diabetes mellitus include enhanced bacterial growth in urine caused by glucosuria or decreased urine concentration, decreased neutrophil chemotaxis associated with glucosuria, and decreased inflammatory response and/or urine retention (detrusor muscle weakness) associated with hypercortisolemia. UTI is also common in dogs with thoracolumbar (T-L) disk disease. In a recent study of 92 dogs that underwent surgery for T-L disk disease, 25 (27%) had UTI. Risk factors for UTI in this study included female gender, the inability to ambulate or voluntarily void, lack of perioperative cefazolin administration, and decreased body temperature (<35° C) during the anesthetic period.

### RELAPSES VERSUS REINFECTIONS

Recurrences of clinical and clinicopathologic signs of UTI can be classified into two categories: relapses and reinfec-

tions. Relapses are infections caused by the same species of bacteria; the clinical signs recur relatively shortly after antibiotic withdrawal. In these cases the previous antibacterial treatment has failed to eliminate the organism. Relapses may result from the use of an improper antibiotic or dosage, the emergence of drug-resistant pathogens, or failure to eliminate factors that alter normal host defense mechanisms and allow the bacteria to persist (e.g., bacteria inside a urolith). Relapsing UTIs are frequently associated with a greater antimicrobial resistance than that observed in the original infection. Relapses in male dogs may result from chronic prostatic infections. Because of the blood-prostate barrier, antibiotics must be lipid soluble and have an alkaline or neutral  $pK_a$  (e.g., fluoroquinolones, trimethoprim-sulfa, chloramphenicol, carbenicillin) in order to gain access to the prostate.

Recurrent UTIs may also result from reinfection. In this case the previous antibacterial treatment cleared the first infection, but the urinary tract subsequently became infected with another bacterium. In most cases the interval between reinfections is longer than the interval between relapses (>2-4 weeks). The occurrence of reinfections often indicates that the factors that alter normal host defense mechanisms have not been eliminated. Alternatively, reinfections may be iatrogenic and occur as a result of follow-up catheterization. Reinfections with less invasive bacteria (*Pseudomonas aeruginosa, Klebsiella pneumoniae, Enterobacter cloacae*) generally suggest that the host's immune system is compromised. Similarly, *Corynebacterium urealyticum* UTI in dogs and cats has been associated with preexisting urinary tract disorders (e.g., incontinence and urine retention).

### **Clinical Features**

Inflammation of the lower urinary tract often results in pollakiuria, stranguria or dysuria, and gross or microscopic hematuria. Urinalysis findings compatible with a lower UTI include bacteriuria, hematuria, pyuria, and increased numbers of transitional epithelial cells in the urine sediment. In addition, an increased urine protein concentration and alkaline urine may be observed. However, bacteria as well as other urine sediment abnormalities are not always observed during urine sediment examination in animals with a bacterial UTI, especially if the urine is hyposthenuric or isosthenuric. Ideally, urine bacterial cultures should be performed to confirm the presence and type of bacteria. Research has shown that the testing of canine urine with commercially available dipstick leukocyte esterase assays is not reliable, and the false-negative rate can exceed 10% in the absence of a urine sediment examination. Some urine dipsticks also have a nitrate pad to detect nitrate-reducing bacteria, but this test has also been shown to be inaccurate in dogs and cats.

Cystocentesis constitutes the best way to collect urine for urinalysis and bacterial culture because it prevents urine from being contaminated by bacteria inhabiting the distal urethra, prepuce, or vulva. If urine collected by catheterization, voiding, or bladder expression is cultured, it is important to quantify the number of organisms per milliliter to differentiate a true infection from contamination (see Table

BOX 45-2

Clinicopathologic Findings that Can Be Associated with Bacterial Pyelonephritis in Dogs and Cats

Fever, leukocytosis, renal pain

Cellular casts in urine sediment

Renal failure (i.e., azotemia, inability to concentrate urine, polydipsia-polyuria)

Excretory urogram and ultrasonographic abnormalities (i.e., renal pelvis dilation or asymmetric filling of diverticula, dilated ureters)

Bacteria in inflammatory lesions identified by renal histologic studies

Positive result from bacterial culture of ureteral urine obtained at cystoscopy (Stamey test)

Positive result from bacterial culture of urine obtained after bladder rinsing with sterile saline solution (Fairley test) Positive result from bacterial culture of fluid aspirated from the renal pelvis (pyelocentesis) under ultrasound guidance

41-1). Bacterial antibiotic sensitivity testing should be performed to guide the selection of antibiotic treatment and, in cases of recurrent UTI, help differentiate relapses from reinfections. It may be difficult to differentiate a lower UTI from upper urinary tract involvement (as well as prostatitis), but this should be attempted to prevent renal damage in dogs and cats with pyelonephritis, which requires long-term antibiotic treatment and close monitoring (Box 45-2). Animals with acute bacterial pyelonephritis or prostatitis may manifest nonspecific systemic signs of lethargy, depression, anorexia, fever, and leukocytosis, which rarely occur in the setting lower UTIs. However, these systemic signs are frequently absent in animals with chronic pyelonephritis or prostatitis. Bilateral pyelonephritis may result in renal failure and subsequent azotemia and the loss of urineconcentrating ability. Cylindruria, especially WBC cellular casts, indicates the presence of renal disease and, if coupled with a significant bacteriuria, is highly suggestive of bacterial pyelonephritis. Several tests have been developed to differentiate upper and lower UTIs in people (see Box 45-2); however, these tests are difficult to perform and have not always proved reliable in veterinary medicine.

### **Treatment**

It is important to try to identify those animals with potentially treatable immune system defects or disorders (e.g., diabetes mellitus, hyperadrenocorticism, chronic renal failure, urolithiasis, urachal remnants, excessive perivulvar skin folds or pyoderma, incontinence) that predispose to the development of UTIs. Therefore a complete physical examination should be performed in all animals with signs of a UTI. Similarly, urinalysis and culture should be performed in all dogs and cats with suspected immune system defects. Although antibiotic treatment is the cornerstone of management, the status of host defense mechanisms is thought to be the single most important determinant of the outcome of

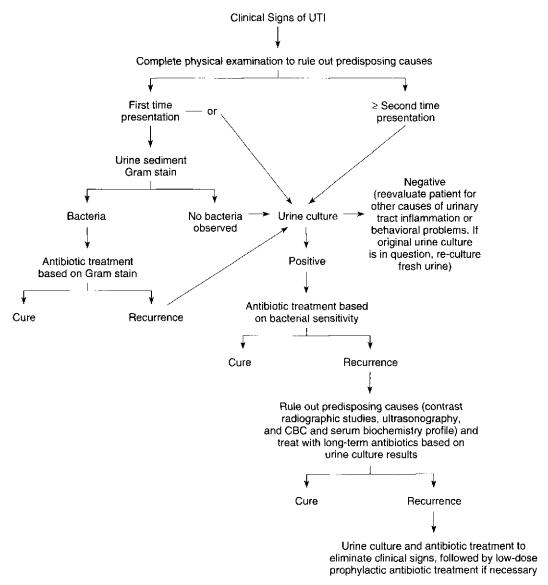

FIG 45-1
Flow diagram for management of urinary tract infections.

treatment for a UTI. Antibiotic treatment should control the pathogenic bacterial growth for enough time to allow host defense mechanisms to prevent colonization of the urinary tract without the need for further antibiotic administration. Although it is advisable to evaluate the bacterial sensitivity to antimicrobial drugs, the treatment of acute, uncomplicated UTIs is often dictated by economic and time considerations. If bacterial sensitivity results are not available, the antibiotic should be chosen on the basis of bacterial identification or the Gram's staining characteristics of the bacteria (Fig. 45-1). Clinical experience at several veterinary teaching hospitals has shown that intelligent guesses can be made regarding bacterial susceptibility to antibiotics. In the absence of bacterial sensitivity testing, the following are the drugs of choice for the treatment of infection with the bacteria listed: E. coli, trimethoprim-sulfa or enrofloxacin; Proteus, amoxicillin; Staphylococcus, amoxicillin; Streptococcus spp., amoxicillin; Enterobacter spp., trimethoprim-sulfa or enrofloxacin; Klebsiella spp., first-generation cephalosporins or enrofloxacin; and Pseudomonas spp., tetracycline (Table 45-3). It should be noted, however, that it is often difficult to predict the sensitivity of gram-negative enteric bacteria. If the identity of the bacteria is unknown, treatment should be determined on the basis of the Gram's staining characteristics (i.e., ampicillin, amoxicillin, or amoxicillin-clavulanic acid for gram-positive bacteria and trimethoprim-sulfa or enrofloxacin for gram-negative bacteria).

The steps to follow in the management of a UTI are given in Box 45-3, and a flow diagram is shown in Fig. 45-1. The duration of therapy for a lower UTI must be individualized and should be based on the cessation of clinical signs and elimination of the abnormal urine sediment as well as negative urine culture results. In general, uncomplicated lower UTIs should be treated for 2 weeks, whereas complicated

<sup>\*</sup>These bacteria are capable of major changes in their susceptibility to antibiotics and are therefore less predictable.

UTIs should be treated for a minimum of 4 weeks. Proper selection of antibiotic therapy can be verified after 3 to 5 days of therapy by determining whether the urine is sterile. The urine sediment, however, may still be abnormal at this time.

Reasons for a poor therapeutic response are listed in Box 45-4. Urine culture and sensitivity testing should always be done in animals with recurrent UTIs. In addition, attempts should be intensified to identify defects in the host's immune system. Double contrast—enhanced cystography and ultrasonography may be used to identify anatomic abnormalities, mucosal lesions of the bladder, or urolithiasis. In intact male dogs semen and prostatic wash cytologic and culture studies as well as ultrasonography should be done to rule out or identify bacterial prostatitis. Excretory urographic, ultraso-

### BOX 45-3

Ideal Steps to Follow in the Management of Urinary Tract Infections in Dogs and Cats

Diagnosis should be determined on the basis of history; urine sediment; and, ideally, urine culture and sensitivity findings.

Select an antimicrobial agent.

Reculture urine in 3 to 5 days to ascertain effectiveness of selected antimicrobial agent.

Examine urine sediment 3 to 4 days before discontinuing antibiotic treatment.

Repeat urinalysis and culture 10 to 14 days after cessation of antibiotic therapy.

Patients with recurrent urinary tract infections should undergo contrast-enhanced radiography and/or ultrasonography, a complete blood count, and serum biochemistry profile to determine whether they have underlying pre-disposing factors.

It may be necessary to treat frequent reinfections with prophylactic doses of antibiotics after the initial inflammation has been cleared up in response to standard-dose antibiotic treatment.

### BOX 45-4

Reasons for Poor Therapeutic Response in Dogs and Cats with Urinary Tract Infections

Use of ineffective drugs or ineffective duration of therapy Failure of owner to administer prescribed dose at proper intervals

Gastrointestinal tract disease or concurrent oral intake of food and drug, resulting in decreased drug absorption Impaired action of drugs, either because bacteria are not multiplying or because they are sequestered in an inaccessible site (e.g., prostate or uroliths)

Failure to recognize and eliminate predisposing causes
Presence of mixed bacterial infections in which only one of
the pathogens is eradicated by antimicrobial therapy
latrogenic reinfection caused by catheterization
Development of drug resistance in bacteria

nographic, and renal biopsy findings may confirm the presence of pyelonephritis; however, results of these studies may be normal in dogs and cats with chronic pyelonephritis. In patients with moderate to marked pyeloectasia, ultrasound-guided pyelocentesis can be used to obtain samples for cytology and culture. Finally, the possibility of otherwise asymptomatic hyperadrenocorticism causing the recurrent UTIs should be considered, especially in animals with infections associated with low numbers of WBCs and RBCs in the urine sediment. Long-term (4 to 6 weeks) antibiotic treatment is required for patients with complicated UTIs, and careful follow-up examinations should be performed in such animals (see Box 45-3). When antibiotic treatment is used

for this period of time, the adverse effects of long-term antibiotic therapy should also be considered. Keratoconjunctivitis sicca and folate deficiency anemia may occur in association with long-term use of trimethoprim-sulfa (although they are rare), and nephrotoxicity is always a concern in animals receiving aminoglycosides, even for a short time.

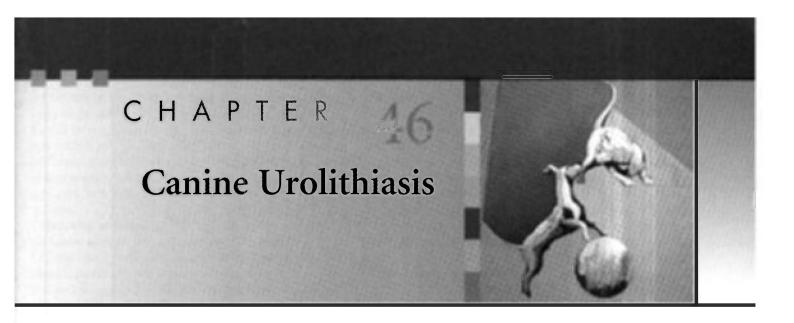

The prognosis for an animal with a complicated UTI, as opposed to an uncomplicated UTI, is always guarded. The single most important treatment for a complicated UTI is correction of the underlying defect in the host defense mechanisms. If predisposing factors cannot be identified or eliminated, relapses and reinfections are common. Low-dose (one third to one half of the conventional daily dose) antimicrobial treatment administered at bedtime (after the last evening void) may be recommended for animals with frequent infections associated with host defense mechanism problems that cannot be cured. This allows the drug to be present in the bladder overnight, supplementing the animal's defense mechanisms. Penicillins are recommended for the treatment of recurrences caused by gram-positive bacteria, whereas trimethoprim-sulfa or enrofloxacin is recommended for the treatment of recurrences caused by gram-negative bacteria. It should be noted, however, that low-dose, longterm antibiotic treatment can predispose the animal to the development of a very resistant UTI.

Urinary acidification (ammonium chloride) has been advocated as adjunctive therapy for lower UTIs because acidic urine provides a less favorable environment for bacterial growth. However, the antimicrobial activity of acidic urine is inferior to that of antibiotics and should not be expected to eradicate infection; ammonium chloride should be used only in conjunction with other modes of therapy. Urinary acidification may also be an effective adjunctive therapy to adjust the urine pH and thereby optimize the efficacy of certain antibiotics (penicillin, ampicillin, carbenicillin, tetracycline, nitrofurantoin). Ammonium chloride (60 to 100 mg/kg) should be given orally twice daily to maintain a urine pH of less than 6.5. The use of ammonium chloride is not without risk, however, especially in male dogs, because oxalate, silicate, urate, and cystine are all less soluble in acidic urine and urolithiasis may result from excessive acidification. In addition, urinary acidification would be contraindicated in dogs with liver or kidney disease. Urinary antiseptics have also been advocated as adjunctive therapy in the control or prophylaxis of lower UTIs. Although they are less effective than specific antimicrobial therapy in eradicating infections, they are probably more effective than urinary acidifiers. Methenamine mandelate is a cyclic hydrocarbon and is the most commonly used urinary tract antiseptic. The dose for dogs is 10 mg/kg, administered orally every 6 hours. In an acidic environment (pH < 6), methenamine hydrolyzes to form formaldehyde. It should be used in conjunction with ammonium chloride to enhance its effectiveness. Methylene blue (tetramethylthionine chloride) is a weak urinary antiseptic agent that used to be common in combination products designed to treat lower urinary tract inflammation in people. These products should not be used in cats, however, because methylene blue has the potential to cause Heinz bodies and hemolytic anemia. Similarly, phenazopyridine, a urinary tract analgesic, should not be used in cats.

Cranberry juice extracts, glycosaminoglycans, and vaccines directed against bacterial fimbria are additional adjunctive treatments that can decrease bacterial adherence to uroepithelium in other species but require further evaluation in the dog before clinical recommendations can be made.

### CHAPTER OUTLINE

GENERAL CONSIDERATIONS

Etiology and Pathogenesis

Clinical features and diagnosis

Treatment

MONITORING THE PATIENT WITH UROLITHIASIS

### **GENERAL CONSIDERATIONS**

Canine urine is a complex solution in which salts (e.g., calcium oxalate, magnesium ammonium phosphate) can remain in solution under conditions of supersaturation. However, supersaturated urine has a potential energy of precipitation, or the tendency to form solids from the dissolved salts. Crystalluria is a consequence of urine supersaturation, and uroliths may form if crystals aggregate and are not excreted. Uroliths may damage the uroepithelium and result in urinary tract inflammation (hematuria, pollakiuria, dysuria-stranguria). They may also predispose the animal to the development of a bacterial urinary tract infection (UTI). If uroliths lodge in the ureters or urethra, urine flow may be obstructed.

Most uroliths in dogs are found in the bladder or urethra; only about 5% are located in the kidneys or ureters. Uroliths are usually named according to their mineral content. Recent data collected at the College of Veterinary Medicine of the University of Minnesota have shown that approximately 38% of canine uroliths are struvite (magnesium ammonium phosphate), 42% are calcium oxalate, 5% are urate, 1% are silicate, 1% are cystine, and 14% are mixed or compound uroliths (i.e., the urolith contains less than 70% of any one mineral type). Crystalline aggregates constitute approximately 95% of the urolith weight, and an organic matrix composed of protein and mucoprotein complexes may constitute as much as 5%. Factors associated with particular types of uroliths are summarized in Table 46-1.

### **Etiology and Pathogenesis**

Conditions that contribute to the crystallization of salts and the formation of uroliths include a sufficiently high concentration of salts in the urine, adequate time in the urinary tract (urinary retention of salts and crystals), a urine pH favorable for salts to crystallize, a nucleation center or nidus on which crystallization can occur, and decreased concentrations of crystallization inhibitors in the urine. The combination of a high dietary intake of minerals and protein and the ability of dogs to produce relatively highly concentrated urine contributes to the supersaturation of urine with salts. In some cases decreased tubular resorption (e.g., calcium, cystine, uric acid) or an increased production secondary to bacterial infection (e.g., ammonium and phosphate ions) also contributes to this supersaturation.

Several theories exist concerning the pathogenesis of uroliths. In the precipitation-crystallization theory, the supersaturation of urine with salts is thought to be the primary factor responsible for initiating nidus formation and sustaining the growth of the urolith. Normal canine urine is supersaturated with several salts. However, the greater the concentration of salts in urine and the less often voiding occurs (e.g., decreased water intake), the greater the chance of urolith formation. Supersaturated urine has a potential energy of precipitation, or a driving force that favors crystal formation. The greater the magnitude of the supersaturation, the greater the potential for crystallization to occur. Conversely, undersaturated solutions have a potential energy of dissolution, such that previously formed crystals dissolve at a rate proportional to the degree of undersaturation.

In other theories of urolith formation, it is thought that substances in urine may promote or inhibit crystal formation. For example, in the matrix nucleation theory an organic matrix substance in urine is thought to promote initial nidus formation. This matrix substance may be albumin, globulin, Tamm-Horsfall mucoprotein, or an immunologically unique hydroxyproline-deficient protein called *matrix substance A*. The proteinaceous matrix substance may promote crystallization by providing a surface where crystallization can occur and by binding crystals together, which may increase their urinary retention. According to another theory, the crystallization inhibitor theory, the absence of a critical inhibitor of crystal formation is considered to be the primary factor that allows initial nidus formation. Examples of

# TABLE 46-1 Factors that Help Predict Urolith Composition

UROLITH TYPE	RADIOGRAPHIC DENSITY (1.0-3.0 scale)	USUAL URINE pH	URINARY TRACT	GENDER PREDISPOSITION	COMMONLY AFFECTED BREEDS	COMMONLY AFFECTED AGES (yr)	CLINICOPATHOLOGIC ABNORMALITIES
Magnesium ammonium phosphate (struvite)	2.5	Neutral to alkaline	Very common, especially urease- producing bacteria (e.g., Staphylococcus, Proteus)	Female (>80%)	Miniature Schnauzers, Bichon Frises, Cocker Spaniels, Miniature Poodles	1-8	Usually none
Calcium oxalate	3.0	Acidic to neutral	Rare	Male (>70%)	Miniature Schnauzers, Miniature Poodles, Yorkshire Terriers, Lhasa Apsos, Bichon Frises, Shih Tzus, Cairn Terriers	5-12	Occasional hypercalcemia
Urate	1.0	Acidic to neutral	Uncommon	Male (>90%)	Dalmatians, English Bulldogs, Miniature Schnauzers (PSS), Yorkshire Terriers (PSS)	1-4	Decreased serum urea, nitrogen, and albumin concentrations and abnormal preprandial and postprandial bile acid concentrations in dogs with PSS
Cystine	1.5	Acidic	Rare	Male (>95%)	Dachshunds, Basset Hounds, English Bulldogs, Yorkshire Terriers, Irish Terriers, Rottweilers, Chihauhaus, Mastiffs, Tibetan Spaniels	1 <i>-7</i>	Usually none
Silicate	2.5	Acidic to neutral	Uncommon	Male (>95%)	German Shepherd Dogs, Golden Retrievers, Labrador Retrievers, Old English Sheepdogs	4-9	Usually none

PSS, Portosystemic shunt.

crystallization inhibitors are citrates, glycosaminoglycans, and pyrophosphates. Decreased concentrations of these substances in urine may facilitate spontaneous crystallization and urolith growth. The extent to which promoters and inhibitors of crystallization are involved in urolith formation in dogs is unknown. In all cases, however, supersaturation of the urine with urolith constituents is essential for uroliths to form.

Struvite uroliths. Struvite or magnesium ammonium phosphate uroliths are common uroliths in dogs (Fig. 46-1). Uroliths that predominantly consist of struvite may also contain a small amount of calcium phosphate (hydroxyapatite) or calcium carbonate. Because most canine diets are rich in minerals and protein, canine urine frequently becomes supersaturated with magnesium, ammonium, and phosphate; however, a UTI is an important factor predisposing to the formation of struvite uroliths in dogs and *Staphylococcus* and *Proteus* are commonly associated pathogens. These bacteria contain urease and are capable of splitting urea into ammonia and carbon dioxide. Hydroxyl and ammonium ions are formed by the hydrolysis of ammonia, which decreases hydrogen ion concentrations in urine, resulting in an alkaline urine and decreased struvite solubility. The

**FIG 46-1 A,** Typical appearance of struvite stones, although struvite stones may also be jack shaped **(B)**. **(B** courtesy Dr. Howard Seim, Colorado State University.)

hydrolysis of urea increases the urine concentrations of ammonium and phosphate (a result of the increased dissociation of phosphorus) ions, which augments urine supersaturation. High urine ammonia concentrations may also damage glycosaminoglycans that prevent bacteria from adhering to the urinary mucosa. Bacterial cystitis also increases the amount of organic debris available as a crystallization surface. Because of their high association with UTIs, struvite uroliths are more common in female dogs (80% to 97% of uroliths in female dogs are struvite). Uroliths in dogs younger than 1 year of age are usually struvite and are also frequently associated with a UTI.

The factors involved in the pathogenesis of struvite uroliths in sterile urine are not known; however, the struvite uroliths that form in cats usually do so in the absence of a UTI. A greater urine-concentrating ability, and therefore a greater degree of urine supersaturation, may be partially responsible for causing uroliths to form in cats and in those dogs without UTIs. In addition, a consistently high urine pH in the absence of a UTI (potentially caused by drugs, diet, or renal tubular disorders) may facilitate struvite urolith formation.

Although struvite uroliths may occur in any breed, those most commonly affected include Miniature Schnauzers, Miniature Poodles, Bichon Frises, and Cocker Spaniels. The high prevalence of struvite uroliths in Cocker Spaniels has led to the suggestion that there is a familial predisposition in this breed (see Table 46-1). Uroliths larger than 1 cm in any dimension are likely to be struvite. In addition, struvite uroliths found in the urinary bladder are most likely to be smooth, blunt-edged or faceted, or pyramidal.

Calcium oxalate uroliths. Calcium oxalate uroliths in dogs are often the monohydrate (whewellite) form (Fig. 46-2, A; see also Fig. 41-3) rather than the dihydrate (weddellite) form (see Figs. 41-4 and 46-2, B). The factors involved in the pathogenesis of calcium oxalate urolithiasis in dogs are not completely understood but frequently involve increased concentrations of calcium in the urine. Hypercalciuria probably occurs most commonly in dogs postprandially and is associated with increased absorption of calcium from the gut. Another potential cause of hypercalciuria is the defective tubular resorption of calcium. Hypercalciuria may also occur secondary to overt hypercalcemia (e.g., that resulting from primary hyperparathyroidism, neoplasia, or vitamin D intoxication); however, this is thought to be an infrequent cause of calcium oxalate uroliths. Treatment with certain drugs (e.g., glucocorticoids, furosemide) as well as dietary supplementation with calcium or sodium chloride may also result in hypercalciuria. An association between hyperadrenocorticism and the development of calcium-containing uroliths has also been identified in dogs. Finally, decreased urine concentrations of glycosaminoglycans, Tamm-Horsfall protein, osteopontine, and/or citrate, which are calcium oxalate crystallization inhibitors, or defective urinary nephrocalcin or increased dietary intake of oxalate (e.g., vegetables, grass, vitamin C) may play a role in the pathogenesis of calcium oxalate urolithiasis in some dogs. The overall preva-

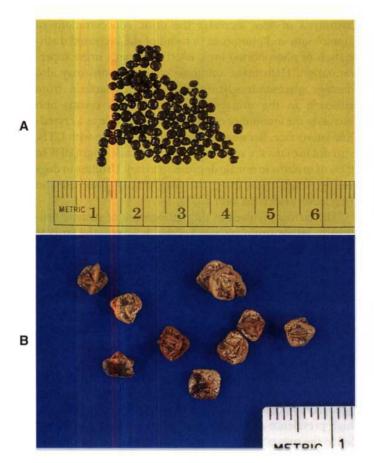

FIG 46-2
Typical appearance of monohydrate calcium oxalate stones
(A) and dihydrate calcium oxalate stones (B).

lence of calcium oxalate uroliths in dogs has increased significantly over the past 10 years and may be related to the increased use of urine-acidifying diets or other unidentified environmental factors.

Approximately 70% of calcium oxalate uroliths are found in male dogs, and Miniature and Standard Schnauzers, Miniature Poodles, Yorkshire Terriers, Lhasa Apsos, Bichon Frises, and Shih Tzus are the breeds commonly affected. Obesity also appears to increase the risk of calcium oxalate urolithiasis. The increased prevalence in male dogs may be related to an increase in the hepatic production of oxalate mediated by testosterone. Conversely, estrogens in female dogs may increase the urinary excretion of citrate. Calcium oxalate uroliths frequently occur in older dogs (mean age: 8 to 12 years), and a concurrent UTI appears to be rare. Calcium oxalate solubility is increased in urine with a pH above 6.5, whereas a urine pH of less than 6.5 favors calcium oxalate crystal formation.

**Urate uroliths.** Most urate uroliths are composed of ammonium acid urate; 100% uric acid and sodium urate uroliths are relatively rare (Fig. 46-3). Uric acid is derived from the metabolic degradation of endogenous purine ribonucleotides and dietary nucleic acids. It is hypothesized that the hepatic transport of uric acid is defective in Dalmatians and some English Bulldogs because uric acid conversion to

**FIG 46-3** Appearance of ammonium urate stones from two different dogs.

allantoin has been found to be decreased in them, even though hepatocyte uricase activities are often adequate. The decreased production of allantoin seen in these breeds results in the increased urinary excretion of uric acid. Normally, allantoin, which is produced through the oxidation of uric acid by uricase, is the major metabolite generated during purine metabolism. In comparison with uric acid, allantoin is quite soluble in urine.

In addition to a decreased hepatic metabolism of uric acid, the proximal tubular resorption of uric acid appears to be decreased in Dalmatians. This increases the uric acid and sodium urate (the salt of uric acid) concentrations in urine. Although urinary uric acid excretion in Dalmatians is approximately 10 times that of other dogs, urate stones form in only a small percentage. For unknown reasons, male Dalmatians are at greater risk of having urate stones than are female Dalmatians. In one published study the male: female ratio for urate stone–forming Dalmatians was reported to be 16.4:1. Approximately 60% of urate uroliths occur in Dalmatians, and, conversely, approximately 75% of the uroliths in Dalmatians are urate uroliths. In addition to Dalmatians, English Bulldogs have an increased incidence of urate uroliths.

Another possible cause of urate stone formation is a decreased glycosaminoglycan concentration in the urine.

Glycosaminoglycans in urine may combine with urate salts, resulting in an overall negative charge and reduced crystallization. High dietary protein is usually associated with an increase in the urinary excretion of both uric acid and ammonium ions. Ammonia, which is produced by renal tubular cells from glutamine, diffuses into the tubular lumen and serves as a buffer for secreted hydrogen ions, thereby forming ammonium ions. Ammonium ions are relatively lipid insoluble and therefore become trapped within the tubular fluid. Uric acid crystallization is facilitated in acidic urine, whereas an alkaline urine appears to favor ammonium urate crystallization. Ammonium acid urate stones may also form in any dog with hepatic insufficiency (e.g., hepatic cirrhosis, microvascular dysplasia, or portosystemic shunt [PSS]) as a result of increased renal excretion of ammonium urates. PSSs are common in Miniature Schnauzers, Yorkshire Terriers, and Pekingese dogs; therefore ammonium acid urate uroliths are more common in these breeds. UTIs, especially those with urease-producing bacteria, may facilitate ammonium acid urate crystallization by increasing urine ammonia concentrations. A UTI may also occur secondary to urolith-induced mucosal irritation.

Silicate uroliths. Silicate uroliths were first reported in the United States in 1976 in association with crystallographic analysis of uroliths. Silicate uroliths frequently, but not always, have a jack shape (Fig. 46-4), although not all jackstones are silicates (ammonium urate and struvite uroliths may also be jack shaped; see Fig. 46-1, B). The factors responsible for the pathogenesis of silicate uroliths are unknown, but their formation is probably related to the dietary intake of silicates, silicic acid, or magnesium silicate. There appears to be a link between the formation of silicate uroliths and the consumption of large amounts of corn gluten or soybean hulls, which can be high in silicates. Many of the reported silicate uroliths in the United States have occurred in male German Shepherd Dogs, Old English Sheepdogs, and Golden and Labrador Retrievers. Most silicate uroliths are diagnosed in dogs 6 to 8 years of age. Alkaline urine appears to increase

silicate solubility, and secondary UTIs may occur as a result of mucosal irritation caused by these jack-shaped uroliths.

Cystine uroliths. Cystinuria, an inherited disorder of renal tubular transport, is thought to be the primary cause of cystine uroliths. The tubular resorptive defect involves cystine and, in some cases, other amino acids (tubular resorption of cysteine, the immediate precursor of cystine, glycine, ornithine, carnitine, arginine, and lysine, may also be decreased). Although the plasma cystine concentrations are normal in these dogs, the concentration of plasma methionine, a precursor of cystine, may be increased. Plasma cystine is freely filtered through the glomeruli and is actively resorbed by proximal tubular epithelial cells in normal dogs. Were it not for the relative insolubility of cystine in urine and the potential for uroliths to form, cystinuria would be of little consequence. Cystine is most soluble in alkaline solutions; therefore cystine stones usually form in acidic urine. Interestingly, cystine uroliths do not form in all dogs with cystinuria; therefore cystinuria is a predisposing, rather than a primary, causative factor. Cystine uroliths (Fig. 46-5) are most frequently observed in male dogs, and Dachshunds are the breed principally affected, but Basset Hounds, Tibetan Spaniels, English Bulldogs, Yorkshire Terriers, Irish Terriers, Chihuahuas, Mastiffs, and Rottweilers also appear to be at increased risk for cystine urolithiasis.

For unknown reasons, cystine uroliths usually do not form in young dogs; the average age at detection is 3 to 6 years. The prevalence of cystine urolithiasis in dogs in the United Kingdom has been reported to be much higher than that seen in dogs in the United States, probably reflecting the increased popularity of affected breeds in the United Kingdom. UTIs may occur secondarily; however, infection is not thought to play a primary role in the pathogenesis of cystine uroliths.

### **Clinical Features and Diagnosis**

The clinical features of urolithiasis depend on the number, type, and location of the stones in the urinary tract. Because

**FIG 46-4** Typical appearance of a silicate stone.

**FIG 46-5** Typical appearance of cystine stones.

most uroliths are located in the urinary bladder, clinical signs of cystitis (hematuria, pollakiuria, dysuria-stranguria) are frequently observed. Mucosal irritation is relatively severe in dogs with jack-shaped uroliths, as opposed to that seen in dogs with solitary, smooth stones. Incomplete voiding (i.e., urine retention), mucosal hyperplasia leading to polyp formation, and sequestration of bacteria within the stone are additional complications associated with urolithiasis. In male dogs smaller uroliths may pass into the urethra, causing partial or complete obstruction with signs of bladder distention, dysuria-stranguria, and postrenal azotemia (depression, anorexia, vomiting). Uroliths frequently lodge in the male urethra at the caudal aspect of the os penis (Fig. 46-6). Occasionally, the urinary bladder or urethra may rupture and result in an abdominal effusion or subcutaneous perineal fluid accumulation and postrenal azotemia. Animals

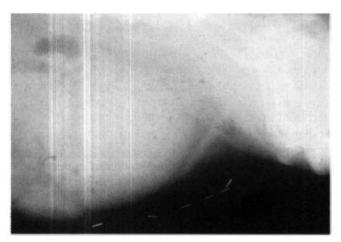

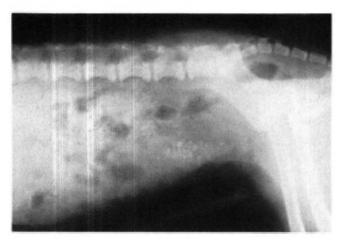

FIG 46-6
Radiograph of a male dog with an opaque urethral calculus at the caudal aspect of the os penis. Note the distended bladder associated with the obstructive uropathy and the staples from a previous cystotomy for urolith removal.

**FIG 46-7**Typical appearance of radiopaque cystouroliths on plain film radiographs. (Courtesy Dr. Philip Steyn, Colorado State University, Fort Collins, Colo.)

with unilateral renal uroliths may be asymptomatic, or they may have hematuria and chronic pyelonephritis. Frequently, chronic kidney disease develops in animals with bilateral renal uroliths, especially if pyelonephritis is also present. Dogs with ureteral uroliths may also be asymptomatic, or they may have hematuria and abdominal pain. Unilateral obstruction of a ureter often results in unilateral hydrone-phrosis without evidence of decreased renal function.

Canine urolithiasis is usually diagnosed on the basis of a combination of historical, physical examination, and radiographic or ultrasonographic findings (Fig. 46-7). In male dogs with dysuria and stranguria caused by urethral stones, attempted passage of a urinary catheter will often be met with a "gritty feeling" of resistance. Regardless of the ease of catheter passage, the diagnosis can usually be confirmed with retrograde positive contrast-enhanced urethrography. In some cases cystouroliths can be detected during abdominal palpation in dogs with signs of cystitis. Plain film radiographs will usually confirm the presence of cystouroliths unless the stones are radiolucent or very small. Doublecontrast-enhanced cystography is a more sensitive diagnostic tool for detecting radiolucent cystouroliths. Finally, ultrasonography can be used to visualize radioopaque or radiolucent uroliths and is the imaging method of choice for diagnosing renoliths and hydronephrosis-hydroureter that can be associated with renoliths.

### **Treatment**

General principles for the treatment of urolithiasis include the relief of any urethral obstruction and decompression of the bladder, if necessary. This can usually be accomplished by the passage of a small-bore catheter, cystocentesis, or dislodgment of the urethral calculi by retrograde hydropulsion. Only rarely will an emergency urethrotomy be necessary. Fluid therapy should be initiated to restore water and electrolyte balance if postrenal azotemia exists. Hyperkalemia is a potentially life-threatening electrolyte disturbance that may occur in association with postrenal azotemia caused by urethral obstruction or rupture of the urinary bladder or urethra. The serum potassium concentration as well as the blood urea nitrogen and creatinine concentrations should be measured in patients with a suspected obstruction. Alternatively, bradycardia and electrocardiographic findings of flattened P waves, a prolonged PR interval, widened QRS complexes, and tall or spiked T waves are suggestive of hyperkalemia and indicate the need for aggressive treatment to lower the serum potassium concentration. Hyperkalemia should be promptly treated according to the regimen outlined in Box 46-1.

The medical dissolution of struvite, urate, and cystine uroliths has been shown to be effective (Table 46-2); however, the choice between the surgical removal of uroliths and medical dissolution is not always clear. Disadvantages of surgery include the need for anesthesia, the invasiveness of the procedure (potential surgical complications), the possibility of incomplete removal of uroliths, and the persistence of underlying causes. Inasmuch as the underlying cause is

BOX 46-1

Electrocardiographic Findings and Treatment Recommendations for Dogs and Cats with Hyperkalemia

### **ECG Findings**

- 1. Bradycardia
- 2. Flattened waves
- 3. Prolonged PR interval
- 4. Widened QRS complexes
- 5. Tall or spiked T waves
- 6. Arrhythmias

### **Treatment Recommendations**

- 1. Fluid therapy with 0.9% saline solution
- Slow IV bolus of regular insulin (0.25-0.5 U/kg), followed by 50% dextrose (4 ml/U of administered insulin), or
- 3. Slow IV bolus of sodium bicarbonate (1-2 mEq/kg), or
- Slow IV balus of 10% calcium gluconate (0.5-1.0 ml/kg while manitoring the ECG)

ECG, Electrocardiogram; IV, intravenous.

usually not eliminated, surgery typically does not lead to a decrease in the rate of urolith recurrence. Advantages of surgery include the fact that the urolith type can be definitively diagnosed, any concurrent or predisposing anatomic abnormalities (e.g., urachal remnants, urinary bladder polyps) can be corrected, and urinary bladder mucosal samples can be obtained for bacterial culture if the urine yields no growth on culture.

Medical treatment decreases the concentration of calculogenic salts in the urine, increases salt solubility in urine, and increases urine volume, which produces urine with a lower concentration of calculogenic salts. The major disadvantage of the medical treatment of urolithiasis is that considerable owner compliance is required for several weeks to months. The cost of medical dissolution is comparable to the cost of surgery because multiple urinalyses, bacterial cultures, and frequent radiographs are required for follow-up. Animals with urolith-induced obstructive uropathy cannot be treated medically, and some uroliths (calcium oxalate, calcium phosphate, silicate, and mixed-composition uroliths) do not respond to medical dissolution. In addition to the medical dissolution of uroliths, voiding urohydropropulsion or catheter urolith retrieval can be used to remove cystouroliths nonsurgically in some animals (Box 46-2; see also Lulich et al., 1992, 1993, for detailed instructions). Lithotripsy, available at some referral centers, has also been used successfully to treat nephroliths and, less commonly, ureteroliths in dogs.

General preventive measures to be taken in addition to the surgical or medical management of uroliths include the induction of diuresis and the eradication of UTIs. Diuresis is important because it lowers the urine specific gravity and the urinary concentration of calculogenic salts. Feeding canned food will help increase water intake. In general, the maintenance of a urine specific gravity of less than 1.020 is ideal, and dogs should be allowed frequent opportunities to void. The urine sediment and pH should be monitored routinely, and UTIs should be treated promptly on the basis of bacterial culture and sensitivity results (see specific instructions in discussion of each type of urolith).

### Guidelines for Urohydropropulsion

- Assess uralith size and shape in relation to animal size: Uraliths must be smaller than the smallest urethral diameter.
  - Smooth uraliths will pass more readily than those with irregular surfaces.
- Sedation facilitates animal positioning. Consider analgesia and muscle relaxation.
- 3. General anesthesia may also be used.
- Moderately distend the bladder with sterile saline solution administered through a urethral catheter (4-6 ml/ kg of body weight), and assess bladder size by abdominal palpation.
- 5. Remove urethral catheter.
- Position the animal so that its vertebral column is vertical.
- Gently agitate the bladder using abdominal palpation to move uroliths into the trigone region.
- Apply steady digital pressure to the bladder to express urine and uroliths.
- 9. Steps 4 through 8 can be repeated as necessary.
- Assess complete urolith removal with follow-up radiographs or double-contrast-enhanced cystograms.

Struvite uroliths. Struvite uroliths can usually be dissolved by feeding the animal a struvite dissolution diet (e.g., Hill's Canine Prescription Diet s/d and Royal Canin canine URINARY SO). It takes an average of 8 to 10 weeks (range: 2 weeks to 7 months) for struvite uroliths to be dissolved in this way. The rate at which uroliths dissolve is proportional to the surface area of the urolith exposed to the undersaturated urine and the presence or absence of a UTI (sterile struvite uroliths will dissolve more rapidly than those associated with a UTI). These diets should not be fed routinely as a maintenance diet and should not be used in pregnant, lactating, or growing animals or after surgery because wound healing may be compromised as a result of the restricted protein in the diet. In addition, because of its high salt content, struvite dissolution diets should not be fed to dogs with congestive heart failure, hypertension, or nephrotic syndrome. In Miniature Schnauzers, the high fat content of the s/d diet may exacerbate any lipid abnormalities and increase the risk of pancreatitis; in this case Hill's Prescription Diet w/d may be used. The dissolution diet should be fed for a minimum of 30 days after the calculi are no longer visible radiographically. It should be noted that these diets will not dissolve nonstruvite uroliths and will not be effective if a UTI persists or if the animal is fed anything in addition to the dissolution diet. Lack of owner compliance with the dietary recommendations (i.e., instructions to feed the dissolution diet only) is indicated if the serum urea nitrogen concentrations remain greater than 10 mg/dl after the diet has been initiated.

In addition to decreasing the concentration of crystalloids in the urine, the elimination of any bacterial UTI is an essential part of the medical treatment of struvite urolithiasis. If infection is present at the start of treatment, antibiotics should be continued throughout the course of the medical dissolution treatment to destroy viable bacteria that may be liberated from the urolith as it dissolves. Antibiotics should be selected on the basis of urine culture and sensitivity findings; in cases of severe or persistent UTIs caused by ureaseproducing bacteria, the urease inhibitor acetohydroxamic acid (Lithostat; Mission Pharmacal, San Antonio, Texas) may be added to the treatment, but it is rarely needed. At a dose of 12.5 mg/kg, administered orally q12h, it may help dissolve struvite uroliths that are resistant to antibiotic and dietary treatment. Adjunctive treatment with urinary acidifiers in conjunction with the struvite dissolution diets is usually not recommended. The most common causes of alkaline urine during diet treatment are a persistent bacterial infection and lack of dietary compliance. The medical treatment of sterile struvite uroliths is the same as that described in previous paragraphs, except that antibiotics are not necessary.

Measures to prevent the recurrence of struvite uroliths include preventing and controlling UTIs, maintaining an acidic urine, and decreasing the dietary intake of calculogenic salts. Hill's Canine Prescription Diet c/d is a good maintenance diet to prevent sterile struvite urolith recurrence because the protein, magnesium, calcium, and phosphorous content is only moderately restricted and it produces an acidic urine. In dogs with recurrent UTIs, predisposing abnormalities (e.g., urachal remnant, urinary bladder polyp) should be identified or ruled out with double-contrastenhanced cystography or ultrasonography. Otherwise, silent hyperadrenocorticism may also result in recurrent UTI (see Chapter 45). Occasionally, long-term, lower-dose prophylactic antibiotic treatment may be necessary to prevent recurrent UTIs. Routine urinalyses should be performed every 2 to 4 months in asymptomatic animals, and follow-up urine cultures performed in animals with clinical signs of lower urinary tract inflammation.

Calcium oxalate uroliths. A medical treatment for the dissolution of oxalate urolithiasis has not yet been developed. A moderate restriction of protein, calcium, oxalate, and sodium intake, with a normal intake of phosphorus, magnesium, and vitamins C and D, is recommended to prevent recurrence of calcium oxalate uroliths after surgical removal (e.g., Hill's Canine Prescription Diet u/d is recommended for this). Increased dietary sodium intake may result in an increase in the urinary excretion of calcium and therefore should be avoided. Potassium citrate, given orally, may help prevent recurrence of calcium oxalate uroliths because citrate complexes with calcium, thereby forming a relatively soluble calcium citrate. In addition, it results in mild urine alkalinization, which increases the solubility of calcium oxalate. However, because overzealous urine alkalinization may result in the formation of calcium phosphate uroliths, this should be avoided. The recommended dose of potassium citrate is 40 to 75 mg/kg, administered orally q12h.

Thiazide diuretics have also been recommended to decrease the urinary excretion of calcium; hydrochlorothiazide (2 mg/kg, administered orally q12h) has been shown to reduce urine calcium excretion in dogs. This effect was enhanced by combining the treatment with the u/d diet.

Urate uroliths. The medical dissolution of urate uroliths that are not associated with hepatic insufficiency (e.g., PSSs) should include a diet low in protein and nucleic acids, alkalinization of the urine, xanthine oxidase inhibition, and the elimination of UTIs. Hill's Canine Prescription Diet u/d has a reduced protein and purine content and produces alkaline urine; therefore it is recommended for the dissolution and prevention of urate uroliths. The u/d diet decreases the hepatic formation of urea and hence renal medullary hypertonicity and urine-concentrating ability. In addition, allopurinol, a competitive inhibitor of the enzyme xanthine oxidase, which converts hypoxanthine to xanthine and xanthine to uric acid (Fig. 46-8), should be administered orally at a dose of 10 to 15 mg/kg q12h or once daily, and, if necessary, sodium bicarbonate or potassium citrate should be administered orally to maintain a urine pH of 7.0. The dose of the urine alkalinizer has to be individualized for each animal. Potassium citrate is available in a wax matrix tablet (Urocit-K; Mission Pharmacal, San Antonio, Texas). Treatment can be started with a one-quarter tablet q8h and the dosage adjusted up or down based on the urine pH. Higher doses of allopurinol especially if combined with higher protein diets, increase the risk of xanthine urolith formation. It is

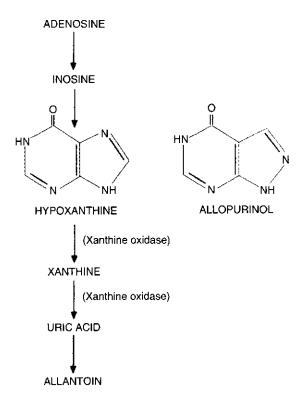

FIG 46-8
Metabolism of purine adenosine and a comparison of the structures of hypoxanthine and allopurinol.

unknown if the long-term use of allopurinol to prevent the recurrence of urate uroliths increases the risk of xanthine uroliths. The benefits of allopurinol may, however, outweigh the risks in animals that have had multiple episodes of urate urolithiasis. Just as in the management of struvite uroliths, any UTI should be appropriately treated because urease-producing organisms will increase the urine ammonium ion concentration and potentiate ammonium urate crystal production.

In dogs with urate urolithiasis secondary to severe hepatic insufficiency, the underlying disorder should be corrected if possible. If hepatic function can be improved (e.g., surgical correction of a PSS) and the urine becomes undersaturated with ammonium and urate ions, uroliths may dissolve spontaneously. Even though spontaneous dissolution after surgical correction of a PSS is possible, it is usually recommended that a cystotomy be performed to remove uroliths at the time of PSS correction. In dogs with inoperable PSS or microvascular dysplasia, the k/d or l/d diet may be used to help decrease urine saturation with ammonium urate and reduce signs of hepatoencephalopathy.

**Silicate uroliths.** Although the medical dissolution of silicate uroliths is not yet feasible, recommended ways to decrease recurrence after surgical removal include a dietary change, increasing the urine volume, and urine alkalinization. Hill's Canine Prescription Diet u/d may be beneficial because it contains low amounts of silicates and produces alkaline urine. In addition, in certain regions soil may contain high concentrations of silicate; therefore the consumption of dirt and grass should be discouraged.

Cystine uroliths. Recommendations for the medical dissolution and prevention of cystine uroliths include a reduction in the dietary intake of protein and methionine, alkalinization of the urine, and the administration of thiolcontaining drugs. Hill's Canine Prescription Diet u/d is appropriate because it has a very low protein content, produces alkaline urine, and decreases the urine-concentrating ability. Urine pH should be maintained at approximately 7.5, with potassium citrate given orally if necessary. Treatment can be started with a one-quarter tablet q8h and the dosage adjusted up or down depending on the urine pH (see urate section above). Sodium bicarbonate or sodium chloride supplementation should be avoided because the resulting natriuresis may enhance cystinuria. d-Penicillamine forms a disulfide compound with cysteine and therefore decreases the cystine content of the urine (Fig. 46-9). This disulfide compound is approximately 50 times more soluble than cystine in urine. d-Penicillamine may interfere with surgical wound healing, and treatment should not be initiated earlier than 2 weeks after surgery. Other possible infrequent or rare adverse effects of d-penicillamine include immune complex glomerulonephritis, fever, and skin hypersensitivity. Another thiol-containing drug, N-(2-mercaptopropionyl)-glycine (MPG), increases the solubility of cystine in urine by means of a disulfide exchange reaction similar to that produced by d-penicillamine and may have fewer adverse effects. The dose of MPG recommended for dogs for urate urolith dis-

FIG 46-9
Structures of cystine, cysteine, d-penicillamine, and cysteine-penicillamine disulfide.

solution is 15 to 20 mg/kg, administered orally q12h. Thiol-containing drugs should be used along with Hill's Canine Prescription Diet u/d if necessary to prevent cystine urolith formation.

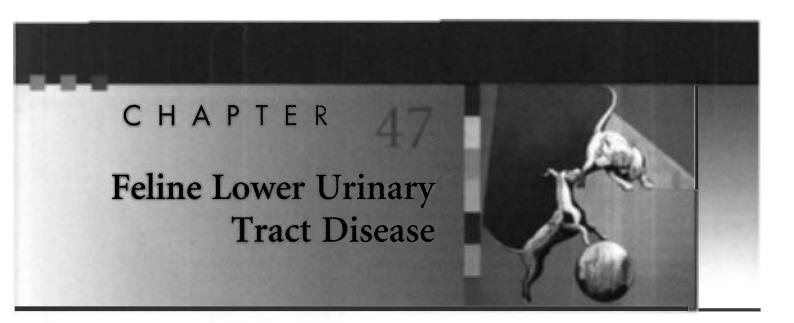

## MONITORING THE PATIENT WITH UROLITHIASIS

Whenever medical dissolution of uroliths is being attempted, the patient should be reexamined at least monthly. A complete urinalysis should be performed, and abdominal radiographs or ultrasonography should be done to assess urolith size. If urinalysis findings are suggestive of a UTI, bacterial culture and sensitivity testing should be performed and antibiotic treatment initiated or adjusted accordingly. If the urolith has not decreased in size after 2 months of dissolution treatment, the clinician should reassess owner compliance, the control of infection, and urolith type and consider removing the urolith surgically.

Uroliths recur in up to 25% of dogs, and it is not uncommon for individual dogs to have three or more episodes of urolithiasis in their lifetimes. The likelihood of recurrence appears to be greatest in dogs with metabolic uroliths (calcium oxalate, urate, and cystine uroliths) or a familial predisposition (e.g., Miniature Schnauzers with struvite uroliths). Therefore appropriate preventive measures and frequent reevaluations are important in such dogs.

### CHAPTER OUTLINE

Etiology and Pathogenesis Clinical Features and Diagnosis Management

Feline lower urinary tract disease (FLUTD) is characterized by one or more of the following clinical signs: pollakiuria, hematuria, dysuria-stranguria, inappropriate urination, and partial or complete urethral obstruction. These clinical signs have historically been termed *feline urologic syndrome*; however, this syndrome is not a single disease entity. The definition of the syndrome has varied among studies and authors, and it is difficult to interpret the literature without a broader definition that includes all disorders associated with FLUTD.

FLUTD has been reported to occur in 0.34% to 0.64% of all cats, and it is thought to be the reason for 4% to 10% of all feline admissions to veterinary hospitals. It appears to be equally prevalent in male and female cats, although overweight cats are thought to be at higher risk for FLUTD. Indoor cats are also reported to be more predisposed to FLUTD than outdoor cats; however, because the urination habits of indoor cats are more closely observed than those of outdoor cats, this may be an observational difference. Most feline lower urinary tract disorders occur in cats between 2 and 6 years of age, with a higher prevalence in the winter and spring months. Between 30% and 70% of cats that have one episode of FLUTD will have a recurrence.

The reported mortality rates for cats with FLUTD range from 6% to 36%. Hyperkalemia and uremia are major causes of death in male cats with urethral obstruction; however, some cats with recurrent FLUTD are euthanized because their owners are unwilling to incur the expense of repeated treatment, diagnostics, or hospitalization necessary to relieve urethral obstruction. Chronic kidney disease (CKD) secondary to ascending pyelonephritis is a possible long-term sequela or complication of FLUTD, especially if there have been repeated urethral catheterizations.

### **Etiology and Pathogenesis**

FLUTD can be divided into two broad categories according to the presence or absence of an identifiable cause of the urinary tract disease. Uroliths, urinary tract infection (UTI), anatomic abnormalities (e.g., urachal remanants, urethral strictures), trauma, irritant cystitis, neurologic disorders, behavioral abnormalities, and neoplasia can all cause or mimic FLUTD. In many cases, despite a thorough diagnostic evaluation, the cause of FLUTD remains unknown and is classified as idiopathic.

**Uroliths.** FLUTD may occur in association with uroliths, microcalculi, and/or crystal-containing mucous urethral plugs. Struvite and calcium oxalate are the most common feline uroliths. As with canine urolithiasis, there must be a sufficiently high concentration of urolith-forming constituents in the urine, a favorable pH, and adequate time in the urinary tract for crystals/uroliths to form.

Approximately 45% of the uroliths in cats consist either entirely or predominantly of struvite. Most struvite uroliths form in the urinary bladder of young cats, and in contrast to dogs, most feline struvite uroliths form in sterile urine. When a bacterial infection is present, the most common organism is a urease-producing *Staphylococcus* sp. Tamm-Horsfall mucoprotein, secreted by the renal tubules, is the major protein found in feline struvite uroliths. It may also play a role in the pathogenesis of urethral plugs that may contain struvite crystals.

Urethral obstruction is more common in the male cat; the length and diameter of the urethra play a relevant role in this. Many obstructions are caused by mucus- and/or struvite-containing plugs that lodge in the penile urethra. Uroliths may lodge in any portion of the urethra, including sections proximal to fibrous connective tissue strictures resulting from previous injuries. Local inflammation that develops in response to urethral calculi or plugs may exacerbate the obstruction by causing urethral edema. Iatrogenic trauma created by urethral catheterization may also cause urethritis or inflammation of the periurethral tissue, leading to urethral compression.

In addition to struvite uroliths, other types of uroliths, including calcium oxalate and urate stones, can cause signs

of FLUTD. Calcium oxalate uroliths account for approximately 45% of feline uroliths, and urate uroliths constitute approximately 5%. According to one study, Burmese, Persian, and Himalayan cats may be at higher risk for calcium oxalate urolithiasis. Calcium oxalate uroliths are also more common in neutered male cats than in female cats, their prevalence is higher in older animals, and they occur more frequently in the kidneys than struvite uroliths do. Calcium oxalate uroliths are becoming more prevalent in cats, and this may be related to the widespread use of acidifying diets designed to prevent struvite-related FLUTD. Epidemiologic studies indicate that cats fed diets low in sodium or potassium or formulated to maximize urine acidity have an increased risk of developing calcium oxalate uroliths but a decreased risk of developing struvite uroliths. Another retrospective study suggested that feeding cats urine-acidifying diets, feeding cats a single brand of cat food, and maintaining cats in an indoor-only environment were factors associated with the development of calcium oxalate urolithiasis. The increase in prevalence of calcium oxalate uroliths in cats may also correlate with the observation that cats are living longer lives than they were 10 to 15 years ago. Finally, because the prevalence of calcium oxalate uroliths is also increasing in people and dogs, there may be unidentified environmental factors common to all three species influencing the development of these uroliths.

**Urinary tract infection.** A primary bacterial infection of the feline urinary tract, although rare in young cats compared with dogs, may also cause the clinical signs observed in FLUTD. Usually, UTI will occur secondary to altered normal host defense mechanisms that allow bacteria to colonize the bladder or urethra. Complete voiding (bladder content washout) is a major host defense mechanism against bacterial infection. Therefore anatomic abnormalities, partial obstructions, or detrusor atony that may interfere with normal voiding can result in an increased urine residual volume. Chronic inflammation of the urinary bladder with fibrosis and thickening of the bladder wall may also cause decreased detrusor tone and incomplete voiding. Perhaps the most important factor predisposing to the development of a secondary bacterial cystitis in association with FLUTD is urethral catheterization (especially placement of indwelling urinary catheters) combined with fluid therapy and the formation of dilute urine that has decreased antibacterial properties.

From time to time, researchers have implicated viruses, including feline calicivirus, bovine herpesvirus 4, and feline syncytia-forming virus, in the pathogenesis of FLUTD. The finding of bovine herpesvirus 4 antibodies in cats and the detection of calicivirus-like particles in the crystalline-mucous urethral plugs of male cats have sparked renewed interest in the possibility of a viral component in the syndrome (Osborne et al., 1999). Whether viruses play a major role remains to be determined.

Miscellaneous causes of feline lower urinary tract disease. In previous studies of cats with naturally occurring FLUTD, approximately 25% had vesicourachal diverticuli (Fig. 47-1). These may be congenital or acquired;

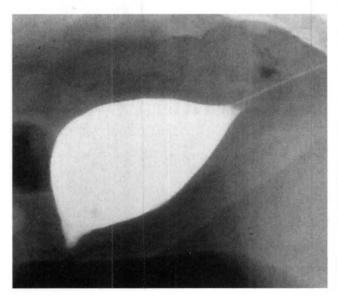

FIG 47-1
Positive-contrast—enhanced cystogram of a feline bladder showing a urachal remnant.

the acquired diverticuli are observed primarily in cats older than 1 year, with a mean age of 3.7 years. Male cats are twice as likely to acquire the abnormality as female cats, and increased intravesical pressure and bladder inflammation during urethral obstruction may play a major role in its pathogenesis. Although a urachal diverticulum may be an incidental finding in an asymptomatic cat, hematuria and dysuria are frequently noted clinical signs. Vesicourachal diverticuli are currently thought to develop secondary to FLUTD and increased intravesical pressure and are not thought to be a major initiating factor.

Idiopathic feline lower urinary tract disease. In large retrospective studies of cats with FLUTD conducted at the University of Minnesota and Ohio State University, a cause could not be found in 54% and 79% of the cats, respectively. Researchers at Ohio State University have found numerous similarities between cats with idiopathic FLUTD and women with interstitial cystitis. These similarities include chronic irritative voiding patterns, sterile urine, a prominent bladder mucosal vascularity with spontaneous hemorrhages observed during cystoscopy, decreased mucosal production of glycosaminoglycan, and increased numbers of mast cells and sensory afferent neurons in bladder mucosal biopsy samples. The cause of interstitial cystitis in women is also unknown. A decreased urine volume and decreased frequency of urination may facilitate the development of FLUTD. Possible causes of a decreased urine volume and frequency of urination include a dirty or poorly available litter box; decreased physical activity as a result of cold weather, castration, obesity, illness, or confinement; and decreased water consumption because of water taste, availability, or temperature. Stress may also contribute to the development of the clinical signs of urinary tract disease. Increased plasma concentrations of noradrenaline have been

documented in cats with idiopathic FLUTD. Increased noradrenaline could increase uroepithelial permeability, increase nociceptive nerve fiber (C-fiber) activity, and activate neurogenic bladder inflammatory responses. Furthermore, decreased cortisol concentrations have been observed when corticotropin-releasing factor and adrenocorticotropic hormone concentrations are increased in cats with idiopathic FLUTD, indicating the possibility of reduced adrenocortical reserve. Although the role of stress is difficult to prove, it is often implicated; the history provided by owners frequently points to a recent association with boarding, cat shows, a new pet or baby in the home, a vacation, or cold or rainy weather. Additional stressors in multiple cat households may include intercat aggression brought on by competition for access to water, food, litter boxes, and space.

### **Clinical Features and Diagnosis**

The clinical signs of FLUTD depend on the component of the disease complex present (Box 47-1). Unobstructed cats usually have pollakiuria, dysuria-stranguria, and microscopic or gross hematuria, and they urinate in inappropriate places, often in a bathtub or sink (see also Chapter 41). These clinical signs may be readily apparent in cats that live indoors but may be missed in cats that live primarily outdoors.

In male cats with urinary obstruction, the presenting signs depend on the duration of the obstruction. Within 6

Licking at genitalia

Congested penis extended from prepuce Signs of postrenal azotemia/uremia

Depression

Weakness

Anorexia

Emesis

Dehydration

Hypothermia

Acidosis and hyperventilation

Electrolyte disturbances (hyperkalemia)

Bradycardia

to 24 hours, most obstructed cats will make frequent attempts to urinate, pace, vocalize, hide under beds or behind couches, lick their genitalia, and display anxiety. If the obstruction is not relieved within 36 to 48 hours, clinical signs characteristic of postrenal azotemia, including anorexia, vomiting, dehydration, depression, weakness, collapse, stupor, hypothermia, acidosis with hyperventilation, bradycardia, and sudden death, may occur.

On physical examination an unobstructed cat will be apparently healthy, except for a small, easily expressed bladder. The bladder wall may also be thickened. Abdominal palpation may be painful for the unobstructed cat; however, the obstructed cat always resents manipulation of the caudal area of the abdomen. The most relevant finding during physical examination of an obstructed cat is a turgid, distended bladder that is difficult or impossible to express. Care should be exercised when manipulating the distended bladder, however, because the wall has been injured by the increased intravesical pressure and is susceptible to rupture. In the cat with urethral obstruction, the penis may be congested and protrude from the prepuce. Occasionally, a urethral plug is observed to extend from the urethral orifice; in some cases the cat may lick its penis until it becomes excoriated and bleeds.

The diagnosis of urethral obstruction is usually straightforward and is based on historical and physical examination findings. In unobstructed cats with FLUTD, urinalysis usually reveals hematuria; if not, behavioral causes of abnormal urination should be considered (Box 47-2 and Fig. 47-2). Struvite-associated disease is likely in cats in which the initial urine pH is alkaline and struvite crystals are observed in the urine sediment. Radiography or ultrasonography and urine cultures should be employed to rule out or identify overt urolithiasis and a urinary tract infection in cats with suspected struvite-associated disease, especially if there is no response to a magnesium-restricted, acidifying diet (see Fig. 47-2 and the section on management). In cats with FLUTD that have acidic urine, radiography or ultrasonography can help identify or rule out anatomic abnormalities (e.g., thickened bladder wall, polyps, tumors, nonstruvite-associated urolithiasis). Cystoscopy is also a valuable tool in cats with FLUTD. Nonspecific cystoscopic findings include prominent mucosal vascularity and submucosal petechial hemorrhages. Radiography (plain and double-contrast-enhanced cystography), ultrasonography, or cystoscopy and urine culture should be performed in all cats with recurrent FLUTD.

### Management

**Unobstructed cats.** The nature of the treatment for FLUTD depends on the clinical signs at presentation (see Box 47-2 and Fig. 47-2). Unobstructed cats with dysuriastranguria and hematuria will often become asymptomatic within 5 to 7 days of presentation whether therapy is instituted or not. Many cats are treated with antibiotics, and if clinical signs abate, a cause-and-effect relationship is often established in the minds of the clinician and cat owner. The clinician should remember, however, that more than 95%

BOX 47-2

### Diagnostic and Therapeutic Plan for Cats with Lower Urinary Tract Inflammation

- Rule out urethral obstruction; relieve obstruction, if present with no. 2 below.
- Assess degree of hyperkalemia with an electrocardiogram; measure serum urea nitrogen, creatinine, and potassium concentrations; and initiate IV fluid therapy if cat is obstructed and depressed.
- In both obstructed and unobstructed cats, obtain a urine sample by cystocentesis, if possible, for the evaluation of urine pH and urine sediment. Culture urine if there is evidence of a urinary tract infection (pyuria, bacteriuria).
- Manage cats with suspected struvite-associated FLUTD using a diet containing less than 20 mEq of magnesium per 100 kCal, and acidify urine (between 6.2 and 6.4) with ammonium chloride or methionine, if necessary.
- Obtain a urine sample in cats with non-struviteassociated FLUTD or in cats with struvite-associated FLUTD with persistent or recurring clinical signs:
  - a. If there is no evidence of urinary tract infection, examine the bladder using radiography or ultrasonography or examine the bladder and urethra using contrast-enhanced radiography or cystoscopy.
  - b. If there is evidence of urinary tract infection, perform bacterial culture and sensitivity testing and treat with an appropriate antibiotic. If signs persist or recur, examine the bladder using radiography or ultrasonography or examine the bladder and urethra with contrast-enhanced radiography or cystoscopy.
- 6. In cases of idiopathic FLUTD, try antiinflammatory treatment.

Clinical signs (dysuria/stranguria, hematuria, pollakiuria, inappropriate urination) Urinalysis Normal Abnormal (rule out behavioral (most likely abnormality and neurologic causes) is hematuria) Alkaline pH Acidic pH Struvite crystalluria No crystalluria Dietary trial (If bacteria (low Mg and urine or pyruria present) acidification) Quantative urine culture No growth Significant growth Antibiotic trial Response No response/ No response/ Response recurrence recurrence Survey and contrast radiographs or ultrasonography of urinary tract or cysto-urethroscopy Specific findings (e.g., Nonspecific findings (e.g., generalized bladder focal bladder wall thickening, tumor, polyps, uroliths) wall thickening, prominent mucosal vascularity, spontaneous submucosal petechial hemorrhages) Try anti-inflammatory treatment Surgery/biopsy if urine is bacteriologically sterile

FIG 47-2
Diagnostic and therapeutic flow chart for unobstructed cats with lower urinary tract disease.

of young cats with FLUTD have sterile urine and that the same results could be obtained by treating with numerous placebos.

If the initial urinalysis reveals an alkaline urine with struvite crystalluria, imaging of the urinary tract to rule out struvite uroliths is indicated. Urine culture and sensitivity tests should be performed if pyuria or bacteriuria is observed in the urine sediment, and appropriate antibiotics should be administered if urine cultures are positive. Cystocentesis is the ideal way to obtain urine for bacterial culture; if urine is obtained by any other method, a quantitative urine culture should be performed. Several sources of fresh water should be made available to the cat. The litter boxes should also be cleaned frequently and placed in convenient locations.

Hill's Feline Prescription Diet s/d can be used to effectively dissolve struvite uroliths. It takes an average of 36 days for sterile struvite uroliths to dissolve, whereas struvite uroliths associated with urease-producing bacterial infections in cats take an average of 79 days to dissolve. Antibiotic treatment in cats with struvite urolithiasis and a concurrent bacterial urinary tract infection should be determined on the basis of urine culture and sensitivity results and continued throughout the period of dissolution. The diet should be fed for 30 days beyond the point when the uroliths are no longer visible in radiographs.

If struvite crystalluria and alkaline urine recur repeatedly in cats with previous struvite uroliths, longer-term dietary therapy is warranted. Examples of diets that can be used to treat struvite-associated FLUTD as well as prevent recurrence include Hill's Feline Prescription Diet c/d (canned or dry), Science Diet Feline Maintenance (canned or dry), Iams pH/S, Purina UR-Formula Feline Diet, and Waltham Veterinarium Feline Control pHormula Diet. The composition of many over-the-counter cat foods is not constant; therefore it is difficult to make recommendations regarding their use. Ideally, the urine pH, measured 4 to 8 hours after feeding, should be maintained between 6.2 and 6.4. The aforementioned prescription diets are metabolized to form acid ions, which are excreted in the urine; it is rare, therefore, for these prescription diets not to maintain an acidic urine in cats. A urease-producing bacterial infection and dietary indiscretion should be identified or ruled out if alkaline urine is found to persist during dietary therapy.

In most cases of FLUTD, the urine is acidic and no struvite crystals are observed; therefore magnesium-restricted, acidifying diets are not recommended. In cats with persistent or recurrent clinical signs, a urine sample should be obtained by cystocentesis for urine culture, and plain abdominal radiography or ultrasonography, contrast-enhanced radiographic studies of the bladder and urethra, or cystoscopy should be performed to identify or rule out anatomic abnormalities if the urine is bacteriologically sterile (see Box 47-2 and Fig. 47-2). Numerous agents, including antibiotics, tranquilizers, anticholinergics, analgesics, antispasmodics, glycosaminoglycans, amitriptyline, and antiinflammatory drugs (e.g., dimethylsulfoxide, glucocorticoids, and nonsteroidal antiinflammmatory drugs [NSAIDs]), have been recom-

mended for the treatment of FLUTD in cats; however, no controlled studies have demonstrated the efficacy of any of these agents. Oxybutynin and propantheline are antispasmodic drugs that may alleviate pollakiuria in some cats, and buprenophine (0.005 to 0.01 mg/kg administered intravenously or intramuscularly q4-8h) or butorphanol (0.2 to 0.8 mg/kg administered intravenously or subcutaneously q2-6h or 1.5 mg/kg administered orally q4-8h) can be used as an analgesic. It must be kept in mind that in controlled studies, more than 70% of cats with idiopathic FLUTD have appeared to respond to placebo treatments (e.g., lactose, wheat flour).

In cats that will accept the change, switching from a dry diet to a canned diet to help increase water intake and decrease urine concentration is often associated with improvement. Decreasing stress and improving quality of life may also be very important factors in the management of cats with idiopathic FLUTD. Increasing the number of litter boxes and keeping them clean may help decrease stress in multiple cat households. Similarly, providing access to several sources of fresh food and water may help. Cats may also benefit from increased play activities and increased access to private space. Finally, pheromone therapy (Feliway CEVA Animal Health, Libourne, France) may produce a calming effect and help reduce stress.

**Obstructed cats.** In cats with a urethral obstruction, the relative urgency for relieving the obstruction depends on the physical status of the cat. Cats that are alert and not azotemic may be sedated for urethral catheterization without further diagnostic tests or treatment; however, in a depressed cat with urethral obstruction, the serum potassium concentration should be measured in-house or an electrocardiograph rhythm strip should be evaluated to assess the degree of hyperkalemia (see Box 46-1) and an intravenous (IV) catheter should be placed for the administration of normal (0.9%) saline solution before establishing urethral patency. If the electrocardiogram or blood tests confirm the presence of hyperkalemia, the cat should be treated aggressively to decrease serum potassium concentrations or counteract the effects of hyperkalemia on cardiac conduction (see Box 46-1).

The degree of restraint required for urethral catheterization depends on the cat's temperament and physical status. Physical restraint in a towel or cat bag, with or without the topical application of lidocaine, may be all that is required in a severely depressed cat. In cats requiring more restraint, ketamine HCl (1 to 2 mg/kg administered intravenously), an ultra–short-acting barbiturate (IV thiamylal sodium or thiopental sodium, 1 mg/kg titrated to effect), or propofol 6.6 mg/kg administered IV slowly over 60 seconds) may be used to effect. Because ketamine is eliminated by the kidneys, low IV doses (10 to 20 mg total) are frequently adequate for restraint. The administration of additional doses of ketamine should be avoided in severely azotemic cats.

A urethral obstruction may be relieved in some cases by penile massage and gentle expression of the bladder. If this does not result in urine flow, palpation of the urethra per rectum may dislodge a urethral plug or calculus. Sterile isotonic saline solution, administered through well-lubricated catheters or cannulas, should be used to hydropulse urethral plugs into the bladder. A variety of cannulas and catheters may be used for this purpose; however, nonmetal catheters with smooth, open ends are preferred to prevent iatrogenic damage to the urethral mucosa. Use of a strict aseptic technique is essential to prevent bacterial UTIs. If catheterizing the bladder proves difficult, cystocentesis with a 22-gauge or small needle may be performed to decrease the intravesical pressure and allow for the urethral obstruction to be backflushed into the bladder.

Indications for the placement of indwelling urinary catheters in male cats with obstructions that have just been relieved include the following: (1) an inability to restore a normal urine stream, (2) an abundance of debris that cannot be extracted via repeated bladder lavage, (3) evidence of detrusor atony in cats that cannot be manually expressed four to six times per day, or (4) intensive care of critically ill animals in which urine formation is being monitored as a guide to fluid therapy requirements. When an indwelling urinary catheter is necessary, again, strict aseptic technique should be used during placement. A soft red rubber feeding tube (3F to 5F) should be used; placing the feeding tube in the freezer for 30 minutes before use facilitates its passage. The catheter should be inserted only as far as the neck of the bladder; catheter passage should be stopped as soon as urine can be aspirated from the catheter. A closed urine-collection system should be used, and the catheter should be sutured to the prepuce and left in place for as short a time as possible (2 to 3 days is the average). An Elizabethan collar or tape hobbles are needed to prevent the cat from chewing out the sutures and removing the catheter. Phenoxybenzamine or prazosin treatment is often initiated at this time to decrease urethral spasms that can be stimulated by the indwelling catheter. Prophylactic antibiotic treatment is not recommended; however, the urine sediment should be examined daily for bacteria and white blood cells, and the urine cultured if necessary. Secondary bacterial UTIs are common in cats with indwelling urinary catheters receiving IV fluids to promote diuresis.

The degree of postrenal azotemia should be assessed by measuring the serum urea nitrogen, creatinine, and potassium concentrations. IV fluid therapy is indicated, especially in cats with azotemia. Maintenance therapy (approximately 60 to 70 ml/kg/day) and replacement therapy (percentage of dehydration  $\times$  body weight [in kilograms] = liters to administer) should be administered intravenously over 24 hours. The subcutaneous administration of a balanced electrolyte solution is an acceptable mode of fluid therapy in some cats once the initial uremic crisis is under control. Measurement of the urine volume every 4 to 8 hours will facilitate the administration of correct replacement therapy. A largevolume, postobstructive diuresis may develop in some cats, and IV fluid replacement therapy is essential in these animals. Serum urea nitrogen, creatinine, and serum electrolyte concentrations should be reassessed as needed, depending on

the degree of azotemia and the response to treatment, to ensure the adequate recovery of renal function. Occasionally, hypokalemia occurs in a cat with a prolonged and severe diuresis. In addition, if severe hematuria persists, the hematocrit should be monitored once or twice daily.

Detrusor atony is fairly common in cats obstructed for more than 24 hours and is associated with bladder over-distention. If the bladder can be expressed four to six times per day, an indwelling catheter may not be necessary. If the bladder cannot be expressed at least four times per day, an indwelling catheter is indicated. Bethanechol (2.5 mg q8h administered orally) may be administered to stimulate detrusor contractility only after the finding of a wide urine stream or the placement of an indwelling urinary catheter has confirmed that the urethra is patent. Acepromazine and phenoxybenzamine can significantly lower intraurethral pressures in anesthetized, healthy, intact male cats, and therefore these drugs may also be helpful in the management of a functional urethral obstruction in cats with FLUTD.

Perineal urethrostomy is rarely required for the emergency relief of a urethral obstruction. If the obstruction cannot be relieved by medical means, the condition of uremic cats must be stabilized before surgery is performed. Repeated cystocentesis should be done to keep the bladder empty until hyperkalemia, acidosis, and uremia resolve. Elective perineal urethrostomies are occasionally advisable in male cats with recurrent obstructions to decrease the likelihood of death from postrenal azotemia. However, a perineal urethrostomy does not decrease the risk of recurrence of clinical signs of cystitis, and it has been documented that cats with cystitis that undergo perineal urethrostomics are more susceptible to bacterial UTIs.

Probably the most important aspect of long-term patient monitoring is ensuring that the owner recognizes both the significance and the clinical signs of urethral obstruction. Owners of male cats with urinary obstruction must be warned of the risks of reobstruction, especially during the first 24 to 48 hours after the relief of an obstruction or the removal of an indwelling urinary catheter. Allowing the owner to palpate the distended bladder during the initial examination is a good way to teach him or her how to differentiate pollakiuria, dysuria-stranguria, and an obstruction. Any straining in the litter box should be cause for alarm in a male cat with a history of urethral obstruction, and careful observation for continued voiding of urine is essential for the early detection of a recurrence.

Follow-up urinalysis and urine culture should be performed 5 to 7 days after catheterization in all cats that have been catheterized to relieve a urethral obstruction. Because normal host defenses are bypassed when a catheter is introduced into the bladder, UTIs are common after catheterization, especially if an indwelling urinary catheter has been used. A follow-up urinalysis and urine culture should also be performed in all cats receiving corticosteroids because these may decrease immune system function (and decrease inflammation-related changes in the urine sediment) and predispose cats to the development of bacterial UTIs. Ascend-

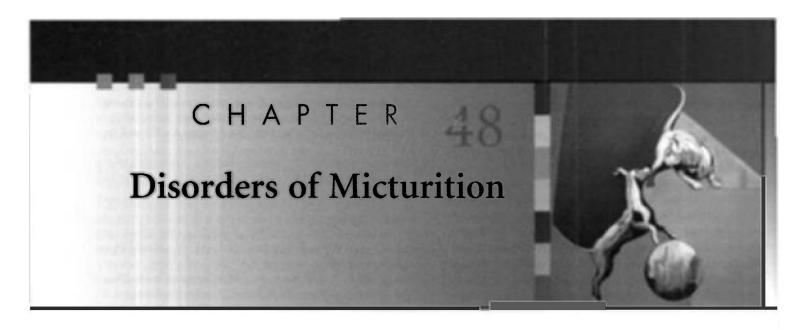

ing pyelonephritis is a significant concern in cats with any UTI, and it is a potential complication of FLUTD, especially if corticosteroids are used. Urethral obstruction caused by struvite uroliths or struvite-containing mucous plugs should be managed with dietary treatment designed to either dissolve the urolith or prevent recurrence, as previously described. Periodic urinalyses to measure pH are beneficial in cats with struvite-associated disease being managed by diet to prevent recurrent episodes. The urine pH 4 to 8 hours after eating should be 6.4 or less. Yearly urinalysis and bacterial culture are especially important in cats with perineal urethrostomies because the normal host defense mechanisms of the lower urethra have been surgically removed in these cats.

The prognosis for male cats with recurrent urethral obstruction is guarded, and perineal urethrostomy should be considered, especially if the second obstruction occurs during medical management designed to prevent recurrence. The prognosis for cats with recurrent nonobstructed FLUTD is fair to good, inasmuch as this syndrome is rarely life-threatening. Pyelonephritis, renal urolithiasis, and CKD are potential sequelae of recurrent nonobstructed FLUTD.

FUNCTIONAL URETHRAL OBSTRUCTION
URETHRAL SPHINCTER MECHANISM
INCOMPETENCE
DETRUSOR HYPERCONTRACTILITY
CONGENITAL DISORDERS
ANATOMIC URETHRAL OBSTRUCTION
Prognosis

Micturition is the normal process of the passive storage and active voiding of urine. Disorders of micturition encompass problems with urine storage (incontinence) and bladder emptying (urine retention). Urinary incontinence is the inappropriate passage of urine during the storage phase of micturition. The most common forms of urinary incontinence occur secondary to either increased detrusor contractility or decreased urethral outflow resistance. Conversely, decreased detrusor contractility or increased urethral outflow resistance can result in urine retention. Armed with an understanding of bladder and urethral neuroanatomy, as well as the mechanism of action of currently available drugs, clinicians are able to effectively control many disorders of micturition.

### PHYSIOLOGY OF MICTURITION

Micturition is controlled by a combination of autonomic and somatic innervation (Fig. 48-1). Parasympathetic inner-

vation to the bladder is provided by the sensory and motor portions of the pelvic nerve that arises from sacral spinal cord segments S1 to S3 (vertebral body L5). The sensory portion relays the sensation of bladder fullness as the stretch receptors associated with detrusor muscle fibers are activated. The motor portion of this parasympathetic innervation predominates during the voiding phase of micturition, with stimulation of the pelvic nerve resulting in the depolarization of pacemaker fibers throughout the detrusor muscle. The subsequent spread of excitation to adjoining muscle fibers through tight junctions of smooth muscle cells leads to contraction of the detrusor muscle.

The S1 to S3 spinal cord segments are also the source of the somatic innervation to the external urethral sphincter via the pudendal nerve. The motor portion of the pudendal nerve causes contraction of the skeletal muscle of the external urethral sphincter under voluntary control. The external urethral sphincter is located predominantly in the midportion of the female urethra and in the membranous portion of the male urethra. The pudendal nerve also has sensory and motor function to the perineal region, including the anal sphincter, vulva, and prepuce.

Sympathetic innervation to the bladder is provided by the hypogastric nerve and is composed of preganglionic fibers exiting spinal cord segments L1 to L4 in the dog (vertebral bodies L1 to L3) and L2 to L5 in the cat (vertebral bodies L2 to L4) and synapsing in the caudal mesenteric ganglion. Adrenergic fibers terminate in the detrusor muscle; stimulation of these fibers results in detrusor muscle relaxation, which facilitates urine storage. Adrenergic fibers innervate the smooth muscle fibers in the trigone and urethra; stimulation of these fibers causes contraction and formation of the functional internal urethral sphincter.  $\alpha$ -Adrenergic receptors also have a modulating effect on the external urethral sphincter.

The normal storage phase of micturition is governed by sympathetic autonomic domination, which causes the detrusor muscle to relax as a result of -adrenergic stimulation and the internal urethral sphincter to contract as a result of -adrenergic stimulation. Voiding is also consciously inhibited by the contraction of striated urethral muscles distal to

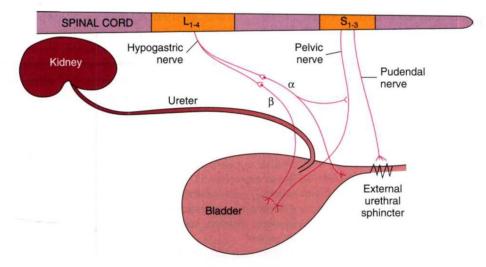

FIG 48-1
Autonomic and somatic innervation of the urinary bladder.

the bladder and involuntarily inhibited by a spinal reflex that tightens the external urethral sphincter when there is a sharp increase in intraabdominal pressure (e.g., during abdominal palpation or bladder expression, barking, coughing, sneezing, retching). Urinary incontinence occurs if the intravesical pressure exceeds the pressure exerted by the urethral sphincters.

Stretch receptors in the bladder send impulses through the pelvic nerve and spinal cord pathways to the thalamus and cerebral cortex when the urinary bladder fills and intramural tension exceeds the threshold. Voluntary control of voiding is mediated by the cerebral cortex through the pons (main micturition center), the cerebellum, and the reticulospinal tracts to the sacral nuclei. The voiding phase of micturition is characterized by parasympathetic activity. In this phase the detrusor muscle contracts secondary to cholinergic stimulation of the motor portion of the pelvic nerve. It is important to note that during this cholinergic-mediated detrusor contraction, the  $\alpha$  and  $\beta$ -adrenergic input to the internal and external urethral sphincters is reflexly inhibited at the level of the pons. When the bladder is empty, the normal sympathetic domination resumes and the detrusor muscle relaxes to allow filling to occur. The normal residual volume of urine after complete voiding is approximately 0.2 to 0.4 ml/kg (with a maximum of 10 ml) in both dogs and cats.

# Etiology and Clinical Features of Disorders of Micturition

Disorders of micturition can be divided into two major categories: those associated with a large or distended bladder and those associated with a small or normal-sized bladder (Table 48-1). Urine retention disorders associated with distended bladders include neurogenic disorders (upper [UMN] and lower [LMN] motor neuron disease, functional urethral obstruction, reflex dyssynergia) and anatomic obstructive disorders. Neurologic disorders may be caused by any condi-

tion that produces compression, damage, or degeneration of the spinal cord or pelvic nerve. Overdistention of the bladder for a prolonged time may also cause a neurogenic incontinence by decreasing bladder detrusor muscle tone (a type of LMN disorder). Dysautonomia in dogs and cats, an autonomic polyganglionopathy, also produces an LMN incontinence that is associated with weak and ineffective detrusor activity. On the other hand, urine leakage or incontinence disorders are usually associated with a small or normal-size bladder caused by increased detrusor contractility or decreased urethral outflow resistance. Congenital abnormalities of the urinary system (e.g., ectopic ureters, vaginal strictures) can also result in urinary incontinence associated with a small or normal-sized urinary bladder. It should be noted that urine leakage can occur with urine retention disorders when intravesical pressure exceeds outflow resistance. This type of urine leakage is referred to as paradoxic or overflow incontinence (discussed in greater detail later).

### DISTENDED BLADDER

Big, distended urinary bladders are usually easily palpated on physical examination, and the ease of bladder expression is an important part of patient assessment. If the distended bladder is easy to express, the underlying problem is usually decreased detrusor contractility. Conversely, if the bladder is difficult to express, increased outflow resistance should be suspected. Both functional (e.g., increased urethral tone caused by increased sympathetic tone or urethral spasm) and anatomic (e.g., urethral uroliths or trigonal masses) problems can cause increased outflow resistance. Urethral catheterization and/or positive contrast urethrography can be used to differentiate functional and anatomic causes of increased outflow resistance.

If neurologic lesions or deficits are detected during neurologic examination, the status of the bladder helps localize

**TABLE 48-1** 

Disorders of Micturition

### DISORDER **CAUSES** Distended Bladder Neurogenic Lesion to S1 to S3 spinal cord segment (at or below fifth lumbar Lower motor neuron disease vertebral body), neoplasia, trauma, cauda equina syndrome Trauma to pelvic nerve, detrusor atony, canine and feline dysautonomia Upper motor neuron disease Lesion cranial to \$1 spinal cord segment (above fifth lumbar vertebral body), intervertebral disk protrusion, neoplasia, trauma, fibrocartilaginous infarct, meningitis Cerebral disease, cerebellar disease, brainstem disease Reflex dyssynergia (detrusor-urethral dyssynergia) Unknown Functional urethral obstruction Urethral muscular spasm, often associated with urethral inflammation or trauma Anatomic outflow tract obstruction Urethral stricture, neoplasia, cystic or urethral calculi, granulomatous urethritis, prostatic disease Small or Normal-Sized Bladder Urethral sphincter mechanism incompetence Deficient bladder/urethral support, hormone-responsive Detrusor hyperreflexia or instability Bladder irritation, urethral irritation Congenital incontinence Ectopic ureters, patent urachus, urethral fistula (rectal or vaginal), pseudohermaphroditism, vaginal strictures

the lesion and classify the injury as either a UMN lesion (above the fifth lumbar vertebral body) or an LMN lesion (at or below the fifth lumbar vertebral body). The most characteristic sign of an LMN lesion affecting the bladder is a distended bladder that is easily expressed. An LMN injury affecting the bladder causes both sphincter and detrusor hyporeflexia; if the lesion involves spinal cord segments S1 to S3, both perineal and bulbospongiosus reflexes of the pudendal nerve are usually absent.

UMN lesions affecting the bladder result in a large, distended bladder that is difficult to express but easy to catheterize. Thoracolumbar spinal cord lesions causing paresis or paralysis are frequent causes of UMN bladder disorders. An animal with a UMN lesion has no voluntary control of micturition, and the urethral sphincter shows reflex hyperexcitability because the somatic efferents in the pudendal nerve are not inhibited, making expression difficult.

Reflex dyssynergia, or detrusor-urethral dyssynergia, is seen primarily in large-breed male dogs. The cause is usually difficult to determine but may include any of several neurologic lesions of the spinal cord or autonomic ganglia. Pathophysiologically, reflex dyssynergia results from the active contraction of the detrusor without relaxation of the internal or external urethral sphincters. Characteristic signs of reflex dyssynergia include normal or near-normal initiation of voiding, followed by a narrowed urine stream. Urine may be delivered in spurts, or flow may be completely disrupted and the dog will often strain to produce urine. After a while the dog will lower its leg and then often begins dribbling

urine while walking away. It is difficult to express urine from the bladder of a dog with reflex dyssynergia, but urethral catheterization is usually easily accomplished. With reflex dyssynergia, increased outflow resistance occurs when the dog tries to initiate voiding. A similar type of functional urethral obstruction has been described in three male dogs in which resting outflow resistance was increased (Lane, 2000). Prostatitis and a history of urethral calculi were associated with the functional urethral obstruction in two cases, respectively; the third case was diagnosed as idiopathic.

Anatomic outflow obstruction results in a big, distended bladder that is usually both difficult to express and catheterize. In some cases a catheter may be passed around an anatomic urethral lesion relatively easily, and a positive contrast retrograde urethrogram may be necessary to confirm the presence of a lesion.

Incontinence in an animal with a primary urine retention problem is called *paradoxic* or *overflow incontinence*. Urine leakage occurs in this case when intravesical pressure exceeds outflow resistance. Clinical signs associated with a functional or anatomic urethral obstruction include dribbling of urine, straining to urinate without producing urine, restlessness, and abdominal pain. The most common causes of anatomic urethral obstruction are calculi and neoplasia in dogs, and struvite/mucous plugs in cats; however, trigonal masses, urethral strictures, and granulomatous urethritis can also create obstructions to urine flow. Any type of prostatic disease in dogs may produce an outflow tract obstruction. Older male dogs with benign prostatic hyperplasia may be evaluated

because of stranguria and tenesmus; however, bacterial prostatitis, prostatic neoplasia, and prostatic abscesses are more likely causes of a urinary outflow tract obstruction. In patients with decreased detrusor contractility, paradoxic incontinence occurs earlier and at lower intravesicular pressures compared with patients that have either functional or anatomic outflow resistance problems.

### SMALL OR NORMAL-SIZE BLADDER

Causes of urinary incontinence associated with a small or normal-size bladder include increased detrusor contractility and decreased outflow resistance. Increased detrusor contractility is generally associated with bladder and or urethral irritation/inflammation that creates an urge to void that overcomes normal house-trained behavior. These patients often exhibit pollakiuria, dysuria, and stranguria and have inflammatory or hemorrhagic urine sediment findings. Conversely, in patients with decreased urethral outflow resistance, urine leakage is often most pronounced when the animal is asleep or relaxed. The voiding phase of micturition is usually normal in these patients, as is the urinalysis (unless complicated by an ascending urinary tract infection).

Detrusor muscle hypercontractility (also referred to as detrusor instability or urge incontinence) is the inability to control voiding owing to a strong urge to urinate. Inflammation of the bladder or urethra may trigger the voiding reflex by creating a sensation of bladder fullness. Clinical signs of this type of incontinence include pollakiuria, dysuria-stranguria, and frequently hematuria. A bacterial urinary tract infection is the most common cause in the dog, and sterile inflammation of the lower urinary tract is the most common cause in cats. Evidence of a urinary tract infection or inflammation revealed by urinalysis (e.g., bacteriuria, pyuria, or hematuria) initially supports the tentative diagnosis of urge or inflammatory incontinence. If clinical signs persist after appropriate treatment for the urinary tract inflammation has been initiated, further diagnostic studies, including ultrasonography, contrast-enhanced radiography, and cystoscopy, are indicated because infiltrative disease of the bladder (e.g., neoplasia, chronic cystitis), polyps, uroliths, or urachal remnants can result in pollakiuria and stranguria. It should also be noted that detrusor hyperreflexia/ instability may be a primary or idiopathic disorder that is not associated with bladder or urethral inflammation.

The preferred terminology for decreased urethral outflow resistance is urethral sphincter mechanism incompetence (USMI). This urethral sphincter dysfunction is most often observed in spayed, medium- to large-breed female dogs. Decreased tone in collagenous supporting structures of the urogenital tract caused by aging and/or decreased estrogen concentrations is thought to be the primary cause of USMI. Additional causes/complications may include abnormal bladder/urethral position (e.g., pelvic bladder), decreased responsiveness of  $\alpha$ -adrenergic urethral receptors, and obesity. Recently, abnormal caudad bladder movement with

the dog under anesthesia has been identified in bitches with USMI. This is thought to be due to deficient bladder and urethral support mechanism in these dogs. Estrogen and testosterone are believed to contribute to the integrity of urethral muscle tone by augmenting its responsiveness to  $\alpha$ -adrenergic innervation. Thus middle-age to older, spayed female dogs are prone to incontinence because of decreased estrogen concentrations. This incontinence is most pronounced when the animal is asleep or relaxed and often responds to estrogen replacement or α-adrenergic therapy. Less frequently, incontinence develops in male dogs after castration; the condition seems to occur most commonly in dogs castrated at an older age and often responds to α-adrenergic treatment or hormone replacement. Both processes are diagnosed on the basis of history, physical examination findings, urinalysis (lack of evidence of lower urinary tract inflammation), and the animal's response to therapy. Frequently,  $\alpha$ -adrenergic treatment (e.g., phenylpropanolamine) may be combined with hormone replacement treatment in severe cases of USMI.

Urinary incontinence in a young animal with a small or normal-size bladder may be associated with a variety of congenital defects of the urinary or genital systems. The most common defects are ectopic ureters and vaginal strictures, but patent urachus, urethrorectal and urethrovaginal fistulae, and female pseudohermaphroditism have also been associated with urinary incontinence. Ectopic ureters are most commonly observed in female dogs. Breeds in which the prevalence of ectopic ureters is high include Siberian Huskies, Miniature and Toy Poodles, Labrador Retrievers, Fox Terriers, West Highland White Terriers, Collies, and Cardigan and Pembroke Welsh Corgis. Ectopic ureters are rarely seen in cats, but the gender predisposition is reversed (i.e., the prevalence is higher in male than in female cats). USMI is a frequent concurrent problem in dogs with ectopic ureters or vaginal strictures.

The most common clinical sign associated with ectopic ureters is constant dribbling of urine, although dogs and cats with a unilateral ectopic ureter also may void normally. Because 70% of ectopic ureters in dogs terminate in the vagina, vaginoscopy may allow visualization of the opening of the ureter; however, the orifice may be difficult to see even if the vagina is fully distended with air. Intravenous urography and retrograde vaginourethrography are excellent diagnostic tests for characterizing the defect, although a recent study suggested that contrast computed tomography (CT) is the test of choice for the diagnosis of ectopic ureters. In contrast to the incontinence seen in animals with ectopic ureters, incontinence associated with a vaginal stricture is often intermittent, occurring with changes in body position. Vaginal strictures can be diagnosed by digital vaginal examination, vaginoscopy, or contrast-enhanced vaginography.

Incontinence may also be caused by cognitive disorders (CDs), decreased bladder capacity, or decreased mobility in senior animals. Polyuric-polydipsic disorders, such as chronic kidney disease (CKD) in senior animals, also often exacer-

bate incontinence. Likewise, use of diuretic and corticosteroid medications should be avoided, if possible, in incontinent animals because of their negative effects on urine-concentrating ability.

### Diagnosis

Clinical features of disorders of micturition often help the clinician discern the underlying problem. For example, if continuous urinary incontinence has been present from birth, the likely underlying problem is a congenital anomaly. Incontinence associated with hematuria, pollakiuria, and dysuria-stranguria usually indicates the presence of inflammation of the bladder, urethra, or both. Inappropriate dribbling of urine during sleep or relaxation indicates USMI, and leakage of urine in female dogs associated with postural changes may point to the pooling of urine behind a vaginal stricture. Dogs with pelvic bladders, which is a more caudal abdominal location in which the bladder neck is caudal to the pecten of the pubic bone (Fig. 48-2), can also have urethral sphincter incompetence that results in urinary incontinence. All these forms of incontinence are usually associated with a small or normal-size bladder.

Dysuria and stranguria that occur in association with an abnormal or absent urine stream are typical of an obstructive uropathy. Urethral obstructions may be caused by anatomic (e.g., uroliths, tumors) or functional (e.g., reflex dyssynergia) problems. Urinary incontinence that occurs in association with trauma or pelvic surgery is usually neurogenic in origin (LMN disease); if paresis or paralysis is present, the lesion is usually above the fifth lumbar vertebral body and is a UMN lesion. Obstructive uropathies

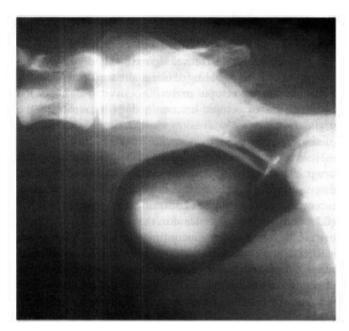

FIG 48-2
Double-contrast—enhanced cystogram showing a pelvic bladder in a 2-year-old spayed female Doberman Pinscher with urethral sphincter mechanism incompetence.

and UMN and LMN disorders result in large, distended bladders.

As noted earlier, incontinence in senior animals may be caused by CDs, a decreased bladder capacity, or decreased physical control. Physical problems in such animals, especially polyuric disorders and disabilities that impair mobility, should be identified and treated. Polyuria and polydipsia can trigger urge incontinence by placing continual stress on the bladder wall and urethral sphincter; however, in these cases the urine volume is large. A normally completely house-broken animal with polyuria and polydipsia may start urinating in the house if it does not have frequent access to the outdoors. If increased thirst and large urine volume are described by the owner, appropriate diagnostic tests should be performed to identify conditions that cause polydipsia and polyuria (e.g., diabetes mellitus, pyometra, CKD, hyperadrenocorticism, hypercalcemia).

Owners frequently mistake submissive urination, which may be a normal behavioral pattern of young dogs, with urinary incontinence. Other voiding patterns that are construed by some owners as incontinence are the urine marking used by male and occasionally female animals and inappropriate elimination behavior problems. The owner's description of the animal's voiding pattern may reveal a behavioral basis for the abnormal micturition, although a complete physical examination and a urinalysis should always be performed to identify or rule out a urinary tract disorder.

### INITIAL EVALUATION

The age of onset, reproductive status of the animal, age at neutering, current medications, and history of trauma or previous urinary tract disorders are important anamnestic points to cover during the history-taking in an animal with any disorder of micturition. The physical examination should include evaluation of the perineum for evidence of urine scalding or staining. A thorough palpation of the bladder to assess its size and wall thickness and a rectal examination to assess anal tone, the prostate gland, the pelvic urethra, and the trigone region of the bladder should be performed in all cases. A digital vaginal examination is also indicated, and vaginoscopy may be used to help identify congenital defects (e.g., vaginal strictures, ectopic ureters) in larger female dogs.

A neurologic examination should include evaluation of the perineal and bulbospongiosus reflexes. The perineal reflex causes the anal sphincter to contract and the tail to ventroflex in response to pinching the perineal skin. The bulbospongiosus reflex causes the anal sphincter to contract in response to gentle compression of the bulb of the penis or the vulva. Both these reflexes depend on an intact pudendal nerve (sensory and motor) and spinal cord segments S1 to S3. If both reflexes are normal, the pudendal reflex arc is intact. Because of their common origin, injury to the pudendal nerve may also affect the pelvic nerve.

Dogs should be walked outside so that the voiding posture and urine stream size and character can be observed. Imme-

diately after the animal has attempted to void, the bladder should be palpated to determine the residual volume (normal residual volume is approximately 0.2 to 0.4 ml/kg). Catheterization is indicated to quantify the residual volume if a large bladder is palpable after voiding (in male dogs, however, behavioral urine marking can make assessment of residual urine volume difficult).

Urinalysis should be performed in all animals with urinary incontinence. If a urine culture is indicated, cystocentesis is the preferred method of collection; however, animals with a distended bladder should be catheterized instead to empty the bladder and prevent the problem of urine leaking from the cystocentesis site. Additional diagnostic testing that can be accomplished at many referral centers includes cystoscopy and urethral pressure profilometry (UPP). Cystoscopy allows direct visualization of the urethral and bladder mucosa and the ability to obtain mucosal specimens for culture and histology. The functional length of the urethral sphincter and the urethral closure pressure can be determined via UPP, which is usually performed in conscious patients. A flexible catheter with a side port is passed through the urethra, and after the bladder has been emptied, the catheter is connected to a pressure transducer and a withdrawal arm (that pulls catheter back through the urethra at a constant rate). Saline is then infused through the catheter as it is withdrawn, and the resistance to flow (pressure) is recorded versus distance traveled. (See additional descriptions of bladder and urethral function testing in Chapter 42.)

### PHARMACOLOGIC TESTING

Frequently, the diagnosis of disorders of micturition is based to some degree on the animal's response to pharmacologic testing or therapy. For example, detrusor hypocontractility should improve in response to a parasympathomimetic drug (e.g., bethanechol), and decreased urethral tone should respond to  $\alpha$ -adrenergic agents (e.g., phenylpropanolamine) or hormone replacement therapy. Increased urethral tone is treated with  $\alpha$ -sympatholytics (e.g., phenoxybenzamine) and striated muscle relaxants (e.g., diazepam). Detrusor hypercontractility often responds to treatment of the underlying inflammatory process, such as bacterial cystitis or urolithiasis; however, smooth muscle antispasmodics (e.g., oxybutynin) and parasympatholytics (e.g., propantheline) may be useful in cases of severe inflammation.

### **Treatment**

### **LOWER MOTOR NEURON DISORDERS**

Animals with LMN diseases resulting from sacral spinal cord lesions or dysautonomia require expression or strict aseptic catheterization of their bladder at least three times per day. Urinalysis or examination of the urine sediment should be performed weekly, and a urine bacterial culture should be performed if there is any evidence of a urinary tract infection.

Care should be taken to prevent urine scalding by applying petroleum jelly to the perivulvar or peripreputial and abdominal skin. Bethanechol may be administered to increase detrusor contractility if the urethra is confirmed to be patent by bladder expression (5–15 mg/dog PO q8h; 1.25–5 mg/cat PO q8h). Adverse effects of bethanechol include salivation, vomiting, diarrhea, or coliclike signs that indicate intestinal cramping. These signs usually appear within 1 hour of drug administration; if they are observed, the dose of bethanechol should be decreased.

To manage detrusor atony, the bladder must be expressed or urinary catheterization done intermittently to keep the bladder empty for a period of days to weeks. A closed urine-collection system should always be used with indwelling catheters. Urinalysis should be performed every 3 or 4 days and a urine bacterial culture and antibiotic sensitivity testing done if there is any evidence of urinary tract inflammation. Bethanechol may be administered to increase detrusor contractility but only after increased outflow resistance has been ruled out.

### **UPPER MOTOR NEURON DISORDERS**

The nature of the management of animals with a UMN lesion affecting the bladder depends on whether the animal has an autonomic bladder. A reflex, or autonomic, bladder often develops 5 to 10 days after a spinal cord injury, and it occurs because stretching of the bladder wall stimulates a local reflex arc that results in detrusor contraction. There is no cortical perception or voluntary control, and initially voiding is usually incomplete, resulting in a large urine residual volume. Treatment in an animal before an autonomic bladder develops should include aseptic catheterization three times per day. The use of corticosteroids for the treatment of neurologic disease may cause polyuria, necessitating more frequent catheterization to prevent overdistention of the bladder. Corticosteroids also predispose animals to urinary tract infections. During the initial stages of treatment, urinalysis or urine sediment examination should be performed every 3 or 4 days, and urine bacterial culture and antibiotic sensitivity testing should be performed if there is evidence of urinary tract inflammation (corticosteroids frequently mask signs of inflammation). Because these animals are usually in pain and reluctant to move, it is important to prevent urine scalding. The use of elevated racks or absorbent bedding is indicated, and petroleum jelly applied around the perineum or prepuce may minimize urine scalding.

After an autonomic bladder develops, the bladder should be palpated after urination to determine the residual urine volume. It may still be necessary to catheterize the bladder two or three times per day to minimize urine stasis. Urinalyses should continue to be done on a monthly schedule (weekly if the animal is receiving corticosteroids), and owners should be instructed to bring in a urine sample if a change in urine color or odor is noted. Nursing care to prevent urine scalding should be continued.

### REFLEX DYSSYNERGIA

Reflex dyssynergia often responds to pharmacologic management; however, a therapeutic response may not be seen for several days. Drugs commonly used include an  $\alpha$ -blocker (e.g., prazosin or phenoxybenzamine), a somatic muscle relaxant (e.g., diazepam), and occasionally bethanechol. Intermittent urinary catheterization should be performed as necessary to keep the bladder small and combat detrusor atony that may be caused by overdistention of the bladder.

Phenoxybenzamine has a slow onset of action, and the dose should be increased only at 3- to 4-day intervals. The urine stream should be evaluated to gauge drug effectiveness. If the stream is weak but continuous and of normal diameter, bethanechol may be used to increase detrusor contractility; however, it must not be used until the functional urethral obstruction has been relieved. If the urine stream is intermittent or narrowed, increased doses of diazepam or phenoxybenzamine or both may be required. Because diazepam has a very short duration of action (approximately 1 to 2 hours when administered orally), administering it 30 minutes before walking the animal sometimes aids in the management of reflex dyssynergia. It may be several weeks before a correct combination of drugs is determined, however, and drug dosages may have to be modified over time. Periodic urinalyses are indicated to detect urinary tract inflammation or infection at an early stage.

Hypotension is the major adverse effect of phenoxybenzamine, and the dose should be decreased immediately if the animal shows any indication of lethargy, weakness, or disorientation. In most cases the dosage of phenoxybenzamine should be increased only if a favorable response is not observed after 3 or 4 days; rapid dose changes should be avoided. Nausea is an adverse effect that can be minimized by administering the medication with a small meal. Glaucoma is a rare complication of phenoxybenzamine treatment in people; it is unknown if this occurs in dogs.

### **FUNCTIONAL URETHRAL OBSTRUCTION**

Nonneurogenic functional urethral obstruction, in which resting as well as voiding urethral pressures are abnormally high, has been associated with prostatic disease; urinary tract infection; urethral muscular spasm; and urethral inflammation, hemorrhage, or edema in dogs and cats. Affected animals have clinical signs and histories similar to those in dogs with reflex dyssynergia. Resting urethral pressure profilometry is usually necessary to differentiate these two syndromes. When treatment of the underlying disorder fails to decrease the increased outflow resistance,  $\alpha$ -blockers (e.g., prazosin or phenoxybenzamine) and skeletal muscle relaxants (e.g., diazepam) can be used.

# URETHRAL SPHINCTER MECHANISM INCOMPETENCE

The treatment of urinary incontinence associated with decreased sphincter tone includes hormone replacement or α-adrenergic drugs (or both). The usual induction therapy for estrogen-responsive incontinence consists of diethylstilbestrol (DES; 0.1 to 1.0 mg total administered orally q24h for 3 to 5 days). The frequency of administration is then decreased to the lowest possible dose that will maintain continence. Some dogs can be successfully tapered to a very low maintenance schedule (e.g., 0.1 to 1.0 mg per dog every 7 to 10 days). Phenylpropanolamine (1.5 to 2.0 mg/kg administered orally q8h) may be used as an alternative drug or in addition to DES. Owners of dogs receiving phenylpropanolamine should be cautioned to observe their dog for hyperexcitability, panting, or anorexia and to decrease the dose if these signs develop. Although initially administered three times per day, in some animals the dosing frequency of timed-release or precision-release phenylpropanolamine can be decreased to a once- or twice-daily schedule. Careful observation by the owner for recurrence of signs usually reveals when the dose needs to be increased. Dogs with increasing resistance to DES pose the greatest worry because the development of estruslike signs and bone marrow toxicity are possible adverse effects of higher-dose DES therapy. Endocrine alopecia is another possible adverse effect. If DESresistant dogs are not concurrently receiving phenylpropanolamine, a trial of it should be instituted before the DES dose exceeds recommended levels. \( \alpha \)-Adrenergic drugs are contraindicated in patients with systemic hypertension, mitral regurgitation, and anxiety disorders.

Urethral sphincter incompetence in neutered male dogs is best treated with  $\alpha$ -adrenergic drugs. If testosterone is to be used, it should be parenterally administered because most testosterone administered orally undergoes rapid hepatic degradation. Depository forms injected intramuscularly may be effective for 4 to 6 weeks. Male dogs receiving testosterone should have regular rectal examinations to evaluate prostate size. Testosterone should not be used in dogs that were previously neutered because of a testosterone-responsive disease (e.g., benign prostatic hypertrophy, perianal adenomas) or behavioral disorders (e.g., aggression).

In those patients with USMI refractory to hormone replacement and/or  $\alpha$ -adrenergic therapy, alternative treatments include gonadotropin-releasing hormone (GnRH) analogues and urethral bulking and surgical procedures. Increased concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) have been documented in spayed dogs, and GnRH analogues will downregulate production/secretion of LH and FSH. Submucosal collagen injections at the level of the internal urethral sphincter via urethroscopy can also be used as an adjunct treatment to increase urethral sphincter tone. Finally, surgical procedures such as colposuspension, cystourethropexy, and formation

of seromuscular urethral slings may benefit patients with USMI that is nonresponive to medical management.

### DETRUSOR HYPERCONTRACTILITY

Smooth muscle relaxants and anticholinergics (e.g., dicyclomine, oxybutynin, propantheline bromide, imipramine, flavoxate) have been used to decrease inappropriate, involuntary detrusor contractions associated with lower urinary tract inflammation, but their use should be reserved for those animals that do not respond to treatment of the primary disorder (e.g., antibiotics for bacterial urinary tract infections). Animals with chronic or recurrent cystitis require a thorough evaluation of the cause of the urinary tract infection (see Chapter 45). Antispasmodics may provide a small degree of relief; however, the identification and elimination of the underlying inflammatory disorder should be the priority. When the detrusor hypercontractility is primary or idiopathic, anticholingeric agents may be beneficial.

### **CONGENITAL DISORDERS**

The correction of congenital defects depends on the nature and extent of the defect. For example, a patent urachus or urachal diverticulum is surgically correctable, as are many forms of ectopic ureters. However, because USMI may occur in conjunction with an ectopic ureter, surgical reimplantation of the ureter does not guarantee continence. The use of  $\alpha$ -adrenergic drugs after surgery increases the likelihood of success. Urethral pressure profilometry can be used to detect USMI and measure the response to  $\alpha$ -adrenergic drugs before surgery.

### ANATOMIC URETHRAL OBSTRUCTION

In animals with an anatomic urethral obstruction, the size and nature of the lesion can usually be determined by retrograde positive-contrast urethrography. The prevention of renal damage secondary to urinary obstruction and the relief of urinary obstruction to prevent detrusor atony resulting from overdistention are the main priorities in dogs and cats with urine outflow tract obstructions. If the obstruction is created by a urethral urolith, retropulsion of the urolith into the bladder may be successful. If the urolith cannot be moved by retropulsion, a temporary or permanent perineal urethrostomy may be necessary.

In dogs with benign prostatic hyperplasia resulting in urethral obstruction, castration usually leads to a rapid decrease in the size of the prostate. The use of estrogens to decrease prostatic size is not recommended because of the potential for systemic adverse effects and the development of squamous metaplasia of the prostate. Surgical drainage and marsupialization may be necessary to manage prostatic abscesses or prostatic cysts. In some cases of prostatic neo-

plasia, partial or complete prostatectomy or radiotherapy may be beneficial; however, prostatectomy is difficult and frequently results in neurologic damage and USMI.

### **Prognosis**

In general, the prognosis for animals with neurogenic forms of urinary incontinence is poor. The long-term prognosis for animals with most types of spinal cord lesions is unfavorable, unless an intervertebral disk protrusion can be successfully decompressed or an extradural mass successfully removed or treated with chemotherapy or radiotherapy. Even if the spinal cord is decompressed, normal micturition may not completely return because the central nervous system has a minimal capacity for regeneration. Damage to the pudendal nerve, pelvic nerve, or sacral nerve roots is associated with a more favorable prognosis because peripheral nerves have a greater capacity to regenerate.

Most of the time, reflex dyssynergia responds to pharmacologic management, but occasionally the underlying disease worsens, making pharmacologic management ineffective. Drug doses should be reevaluated and increased if this happens, but this is not always successful. Diagnostic procedures such as myelography, an epidurography, CT, or magnetic resonance imaging (MRI) may be indicated in these refractory cases. Catheterization using aseptic techniques may be necessary for the long-term management of these animals.

Periodic urinalyses to identify or rule out urinary tract infections constitute an important aspect of follow-up care in an animal with any disorder of micturition. The frequency of the urinalyses depends on the nature of the disorder. Owners can be instructed to evaluate the color and odor of the urinc and to bring in a urine sample immediately if they suspect an infection; however, routine monitoring is the cornerstone of the prevention of severe urinary tract infections. The prognosis for animals with USMI is usually good, although some dogs require multiple drugs for management.

Dogs treated for urge or inflammatory incontinence secondary to a urinary tract infection should undergo follow-up urinalysis or urine bacterial culture studies to confirm that the urinary tract infection has been eliminated. Long-term dietary management may help prevent recurrences in animals with urolithiasis.

The prognosis for dogs and cats with trigonal or urethral neoplasia is usually poor. In most cases, urethral neoplasia is inoperable because the clinical signs (dysuria, stranguria, hematuria, urethral obstruction) are usually not observed until the tumor is invasive. In contrast, most female dogs with granulomatous (chronic active) urethritis respond well to a combination of prednisolone, cyclophosphamide, and antibiotics.

# Drugs Used in Dogs and Cats with Urinary Tract Disorders

DRUG	TRADE NAME	ACTION	DOSE
Allopurinol	Zyloprim	Xanthine oxidase inhibitor	10 mg/kg q8-24h PO (dog)
Aluminum carbonate, aluminum hydroxide	Basal gel, Amphojel	Enteric phosphate binders	10-30 mg/kg q8h PO with or immediately after meals
Amitriptyline	Elavil Anticholinergic effect decreased histami release from mast increased bladder compliance		5-10 mg q24h (evening) PO (cat)
Amlodipine	Norvasc	Calcium antagonist	2.5 mg q24h (dog); 0.625 mg q24h (cat)
Ammonium chloride		Urinary acidifier	100 mg/kg q12h PO (dog); 800 mg mixed with food daily (approximately 1/4 tsp) (cat)
Aspirin		Antiplatelet, anti- inflammatory	0.5-5 mg/kg q12h (dog); 0.5-5 mg/kg q24h (cat)
Azathioprine	lmuran	Immunosuppressant	1-2 mg/kg PO q24h initially, then 0.5- 1.0 mg/kg PO q48h (dogs only)
Benazepril	Lotensin	Angiotensin-converting enzyme inhibitor	0.25-0.5 mg/kg PO q24h
Bethanechol	Urecholine	Cholinergic (increases detrusor contractility)	5-15 mg q8h PO (dog); 1.25-5 mg q8h PO (cat)
Chlorpromazine	Thorazine	Antiemetic	0.25-0.5 mg/kg q6-8h IM, SQ, PO (after rehydration only)
Cimetidine	Tagamet	H <sub>2</sub> blocker	2.5-5.0 mg/kg q12h PO, IV, IM
Cyclophosphamide	Cytoxan, Neosar	Immunosuppressant	50 mg/m <sup>2</sup> PO q48h (dogs); 200-300 mg/ m <sup>2</sup> PO q3wk (cats)
Cyclosporine	Neoral, Sandimmune	Immunosuppressant	3-7 mg/kg q12-24h, adjust dose via monitoring
Diazepam	Valium	Skeletal muscle relaxant	2-5 mg q8h PO

Drugs Used in Dogs and Cats with Urinary Tract Disorders—cont'd

DRUG	TRADE NAME	ACTION	DOSE
Dicyclomine	Bentyl, Bentylol	Antispasmodic, antimuscarinic	0.15 mg/kg PO q8-12h (dog)
Diethylstilbestrol (DES)		Increased urethral sphincter tone	0.1-1.0 mg q24h PO for 3-5 days and then same dose q3-7days (dog); 0.05- 0.1 mg q24h PO q3-5days and then same dose q3-7days (cat)
1,25-Dihydroxychole- calciferol, calcitriol	Rocaltrol	Active vitamin D <sub>3</sub> , decreases parathyroid hormone	1.5-3.5 ng/kg q24h PO
Enalapril	Enacard	Angiotensin-converting enzyme inhibitor	0.5 mg/kg q12-24h PO (dog); 0.25- 0.5 mg/kg q12-24h PO (cat)
Ephedrine		α-Adrénergic, increases urethral sphincter tone	12.5-50 mg q12h PO (dog); 2-4 mg/kg q8-12h PO (cat)
Erythropoietin (r-Hu- EPO), epoetin alfa	Epogen	Stimulate erythrogenesis	35-50 U/kg IV, SQ 3 times/wk or 400 U/kg IV, SQ weekly; adjust dose to PCV of 30%-35%
Famotidine	Pepcid	H <sub>2</sub> blocker	0.5 mg/kg IM, SQ, PO q12-24h
Flavoxate	Urispas	Muscle relaxant	100-200 mg q6-8h
Furosemide	Lasix	Loop diuretic	2-4 mg/kg q8-12h iV, PO
Hydralazine	Apresoline	Arterial vasodilator	0.5-2.0 mg/kg q12h PO (dog); 2.5 mg q24h-q12h PO (cat)
Imipramine	Tofranil	Antimuscarinic, adrenergic agonist, muscle relaxant	5-15 mg PO q12h (dog); 2.5-5 mg PO q12h (cat)
Lisinopril	Prinivil, Zestril	Angiotensin-converting enzyme inhibitor	0.5 mg/kg PO q24h (dog)
Mannitol	Osmitrol	Osmotic diuretic	0.5-1.0 g/kg as 20%-25% solution, slow IV bolus over 5-10 min
N-(2-mercaptopropionyl)- glycine		Disulfide bond formation with cysteine	10-15 mg/kg q12h PO (dog)
Metoclopramide	Regian	Antiemetic	0.2-0.5 mg/kg q8h PO, SQ
Nandrolone decanoate	Deca-Durabolin	Anabolic steroid	1.0-1.5 mg/kg weekly IM (dog); 1.0 mg weekly IM (cat)
Oxybutynin	Ditropan	Direct antispasmodic effect on smooth muscle	0.2-0.5 mg/kg q8-12h PO (dog)
d-Penicillamine	Cuprimine	Disulfide bond formation with cysteine	10-15 mg/kg q12h PO (dog)
Phenoxybenzamine	Dibenzyline	α-Blocker, decreases urethral sphincter tone	0.2-0.5 mg/kg q24h PO (dog); 0.5 mg/kg q24h PO (cat)
Phenylpropanolamine	Propagest	α-Adrenergic, increases urethral sphincter tone	1.5-2.0 mg/kg q8-12h PO
Prazosin	Minipress	α-Blocker	1 mg/15 kg PO q6-8h
Propantheline bromide	Pro-Banthine	Anticholinergic, decreases detrusor contractility	0.25-0.5 mg/kg q8-12h PO
Racemethionine	Uroeze, Methio-Form	Urinary acidifier	150-300 mg/kg/day PO (dog); 1.0-1.5 g/ day PO (cat)
Ranitidine	Zantac	H <sub>2</sub> blocker	2.0 mg/kg q8h PO, IV (dog); 2.5 mg/kg q12h IV, 3.5 mg/kg q12h PO (cat)
Testosterone cypionate	Andro-Cyp	Increased urethral sphincter tone	1.0-2.2 mg/kg q30days IM (dog)
Trimethobenzamide	Tigan	Antiemetic	3.0 mg/kg q8h PO, IM (dog)

PCV, Packed cell volume.

Signalment Clinical Signs

### **POLYURIA AND POLYDIPSIA**

Water consumption and urine production are controlled by complex interactions among plasma osmolality and volume, the thirst center, the kidney, the pituitary gland, and the hypothalamus. Dysfunction in any of these areas results in the clinical signs of polyuria (PU) and polydipsia (PD). In dogs normal water intake is usually less than 60 ml/kg of body weight/24 h, with an upper normal limit of 100 ml/kg. Similar values are used for cats, although most cats drink considerably less than these amounts. Normal urine output varies between 20 and 45 ml/kg/24 h. PD and PU in the dog and cat have been defined as water consumption that exceeds 100 ml/kg/24 h and urine production greater than 50 ml/

kg/24 h, respectively. It is possible, however, for thirst and urine production to be abnormal within the limits of these normal values in individual dogs and cats.

A variety of metabolic disturbances can cause PU/PD (see Box 41-3). Primary polyuric disorders can be classified on the basis of the underlying pathophysiology into primary pituitary and nephrogenic diabetes insipidus, secondary nephrogenic diabetes insipidus, osmotic diuresis-induced polyuria, and interference with the hypothalamic-pituitary secretion of arginine vasopressin (AVP). The most common form of diabetes insipidus is acquired secondary nephrogenic diabetes insipidus. This form includes a variety of renal and metabolic disorders in which the renal tubules lose the ability to respond adequately to AVP. Most of these acquired forms are potentially reversible after elimination of the underlying illness.

Secondary nephrogenic diabetes insipidus results from interference with the normal interaction of AVP and renal tubular AVP receptors, problems with the generation of intracellular cAMP, problems with renal tubular cell function, or loss of the renal medullary interstitial concentration gradient. Primary polydipsic disorders occur in dogs and usually have a psychogenic or behavioral basis for the compulsive water consumption (see the discussion of psychogenic PD, p. 702). A complete discussion of the diagnostic approach to PU/PD is presented on p. 704. An index of suspicion for most of the endocrinopathies that cause PU/PD can be raised after a review of the history, physical examination findings, and results of a complete blood count (CBC), serum biochemistry panel, and urinalysis. Specific tests may be necessary to confirm the diagnosis (Table 49-1). See the appropriate chapters in this section for a more complete discussion of the diagnosis and treatment of each of these endocrinopathies.

Occasionally, the physical examination findings and initial blood and urine tests are normal in dogs and cats with PU and PD. Differential diagnoses in these dogs and cats include diabetes insipidus, psychogenic PD, hyperadrenocorticism,

# Endocrine Disorders Causing Polyuria and Polydipsia in the Dog and Cat

TESTS TO ESTABLISH THE DIAGNOSIS		
Fasting blood glucose, urinalysis		
Urine C/C ratio, low-dose dexamethasone suppression test		
Blood electrolytes, ACTH stimulation test		
Blood calcium/phosphorus, cervical ultrasound, serum PTH concentration		
Serum T₄ and free T₄ concentration		
Modified water deprivation test, response to dDAVP therapy		
' ' '		
Baseline GH or IGF-I concentration, CT or MR scan		
Blood electrolytes, plasma aldosterone concentration		

C/C, Cortisol/creatinine; ACTH, Adrenocorticotropic hormone; PTH, parathyroid hormone; GH, growth hormone; IGF-I, Insulin-like growth factor-I; CT, computed tomographic; MR, magnetic resonance.

mild renal insufficiency without azotemia, and mild hepatic insufficiency, most notably with portosystemic shunts. Hyperadrenocorticism, renal insufficiency, and hepatic insufficiency should be ruled out before performing diagnostic tests for diabetes insipidus or psychogenic PD. Diagnostic tests to consider include evaluating the range of urine specific gravities obtained from several urine samples (discussed in more detail below), tests for hyperadrenocorticism (e.g., urine cortisol: creatinine ratio, low-dose dexamethasone suppression test), liver function tests (e.g., measurement of preprandial and postprandial bile acid levels), determination of the urine protein: creatinine (P/C) ratio, and abdominal ultrasonography. Ideally, all realistic causes of secondary acquired nephrogenic diabetes insipidus should be ruled out before performing tests (especially the modified water deprivation test) for primary pituitary and nephrogenic diabetes insipidus and psychogenic PD.

Critical evaluation of urine specific gravity measured from several urine samples obtained by the client at different times of the day for 2 to 3 days may provide clues to the underlying disorder (Table 49-2). Urine samples should be stored in the refrigerator until they can be brought to the

veterinary hospital for determination of urine specific gravity. Urine specific gravity varies widely among healthy dogs and can range from 1.006 to greater than 1.040 within a 24-hour period. Wide fluctuations in urine specific gravity have not been reported in healthy cats. If the urine specific gravity is consistently in the isosthenuric range (1.008 to 1.015), renal insufficiency should be considered the primary differential diagnosis, especially if the blood urea nitrogen and serum creatinine concentration are high normal or increased (i.e., 25 mg/dl or more and 1.6 mg/dl or more, respectively). Isosthenuria is relatively common in dogs with hyperadrenocorticism, psychogenic water consumption, hepatic insufficiency, pyelonephritis, and partial diabetes insipidus with concurrent water restriction, but urine specific gravities above (e.g., hyperadrenocorticism, pyelonephritis, hepatic insufficiency, psychogenic water consumption) or below (e.g., hyperadrenocorticism, hepatic insufficiency, partial diabetes insipidus) the isosthenuric range also occur with these disorders. If urine specific gravities less than 1.005 (i.e., hyposthenuric) are identified, renal insufficiency and pyelonephritis are ruled out and diabetes insipidus, psychogenic water consumption, hyperadrenocorticism, and hepatic insufficiency should be considered. Primary pituitary and nephrogenic diabetes insipidus are ruled out if the urine specific gravity exceeds 1.020. Urine specific gravities that range from less than 1.005 to greater than 1.030 are suggestive of psychogenic PD.

# **DIABETES INSIPIDUS**

# Etiology

AVP plays a key role in the control of renal water resorption, urine production and concentration, and water balance. AVP is produced in the supraoptic and paraventricular nuclei of the hypothalamus, is stored in and secreted from the posterior pituitary gland in response to an increase in plasma osmolality or decrease in extracellular fluid volume, and interacts with distal tubular and collecting duct cells of the kidney to promote water resorption and the formation of concentrated urine. The defective synthesis or secretion of AVP or an inability of the renal tubules to respond to AVP causes diabetes insipidus.

#### CENTRAL DIABETES INSIPIDUS

Central diabetes insipidus (CDI) is a polyuric syndrome that results from insufficient secretion of AVP to concentrate urine for water conservation. This deficiency may be absolute or partial. An absolute deficiency of AVP, referred to as complete CDI, causes persistent hyposthenuria and severe diuresis. The urine specific gravity in dogs and cats with complete CDI remains hyposthenuric (i.e., 1.005 or less), even with severe dehydration. A partial deficiency of AVP, referred to as partial CDI, also causes persistent hyposthenuria and a marked diuresis as long as the dog or cat has unlimited access to water. During periods of water restriction the urine specific gravity can increase into the isosthenuric range (i.e., 1.008 to 1.015), but typically the urine cannot be concentrated to more than 1.015 to 1.020 even when the animal is severely dehydrated. In any dog or cat with partial CDI the maximum urine-concentrating ability during dehydration is inversely related to the severity of the deficiency in AVP secretion—that is, the more severe the AVP deficiency, the less concentrated the urine specific gravity during dehydration.

CDI may result from any condition that damages the neurohypophyseal system (Box 49-1). Idiopathic CDI is the most common form, appearing at any age, in any breed, and affecting animals of either sex. Necropsies performed in dogs and cats with idiopathic CDI fail to identify an underlying reason for the AVP deficiency. Although CDI is well documented in kittens and puppies, a hereditary form of CDI has not yet been documented. The most common identifiable causes of CDI in dogs and cats are head trauma (accidental or neurosurgical), neoplasia, and hypothalamic-pituitary malformations (e.g., cystic structures). Head trauma may cause a transient (typically lasting 1 to 3 weeks) or permanent CDI, depending on the viability of the cells in the supraoptic and paraventricular nuclei.

Recognized Causes of Diabetes Insipidus in Dogs and Cats

CENTRAL DIABETES INSIPIDUS	NEPHROGENIC DIABETES INSIPIDUS
Idiopathic Traumatic Neoplasia Craniopharyngioma Chromophobe adenoma Chromophobe adenocarcinoma Metastasis Hypothalamic and pituitary malformation Cysts Inflammation Familial (?)	Primary idiopathic Primary familial (Huskies) Secondary acquired (see Box 41-4)

Primary intracranial tumors that are associated with diabetes insipidus in dogs and cats include craniopharyngioma, pituitary chromophobe adenoma, and pituitary chromophobe adenocarcinoma. Metastatic mammary carcinoma, lymphoma, malignant melanoma, and pancreatic carcinoma have been reported to cause CDI in dogs through their presence in the pituitary gland or hypothalamus. Metastatic neoplasia has not yet been reported to be a cause of CDI in cats.

#### **NEPHROGENIC DIABETES INSIPIDUS**

Nephrogenic diabetes insipidus (NDI) is a polyuric disorder that results from impaired responsiveness of the nephron to AVP. Plasma AVP concentrations are normal or increased in animals with this disorder. NDI is classified as either primary (familial) or secondary (acquired). Primary NDI is a rare congenital disorder in dogs and cats, with only a few reports in the literature. The etiology of primary NDI in dogs and cats is unknown, although decreased binding affinity of AVP receptors was identified in a family of Siberian Huskies. Affected puppies showed antidiuretic responses to high doses of synthetic vasopressin (desmopressin [dDAVP]).

# **Clinical Features**

#### SIGNALMENT

There is no apparent breed-, sex-, or age-related predilection for CDI. In one study the age at the time of the diagnosis of CDI in dogs ranged from 7 weeks to 14 years, with a median of 5 years. Similarly, most cats with CDI are domestic short- and long-haired cats, although the disorder has also been documented in Persians and Abyssinians. The age at the time of diagnosis of CDI in cats ranged from 8 weeks to 6 years, with a mean of 1.5 years. Primary NDI has been identified only in puppies, kittens, and young adult dogs and cats

younger than 18 months of age. PU and PD have been present since the clients acquired these pets.

#### **CLINICAL SIGNS**

PU and PD are the hallmark signs of diabetes insipidus and are typically the only signs seen in dogs and cats with congenital and idiopathic CDI and in those with primary NDI. Clients may believe that affected animals are incontinent because of the frequency of urination and loss of normal housebroken behavior. Owners of cats with diabetes insipidus often complain that they need to change the kitty litter more frequently than expected. Additional clinical signs may be found in dogs and cats with secondary causes of diabetes insipidus. The most worrisome are neurologic signs, which may indicate the presence of an expanding hypothalamic or pituitary tumor in the adult dog or cat that has not had head trauma.

# PHYSICAL EXAMINATION

The physical examination findings are usually unremarkable in animals with CDI, although some dogs and cats are thin, presumably because the pet's strong desire for water overrides its normal appetite. As long as access to water is not restricted, the animal's hydration status, mucous membrane color, and capillary refill time remain normal. The presence of neurologic abnormalities is variable in dogs and cats with either trauma-induced CDI or neoplastic destruction of the hypothalamus or pituitary gland. When present, neurologic signs may include stupor, disorientation, ataxia, circling, pacing, and convulsions. Severe hypernatremia may also cause neurologic signs in the traumatized dog or cat with undiagnosed CDI given inadequate fluid therapy (see

Chapter 55). Hyposthenuria in the presence of persistent hypernatremia should raise suspicion for diabetes insipidus.

# **Diagnosis**

The diagnostic workup for PU and PD should initially rule out causes of acquired secondary NDI (see Chapter 41). Recommended initial diagnostic studies include a CBC; biochemistry panel; urinalysis with bacterial culture; abdominal ultrasonography; and a urine cortisol: creatinine ratio, low-dose dexamethasone suppression test, or both. Results of these screening tests are normal in dogs and cats with CDI, primary NDI, and psychogenic water consumption, although a low-normal serum urea nitrogen concentration (5 to 10 mg/dl) may be found. Random urine specific gravity is usually less than 1.006 and is often as low as 1.001 if the dog or cat has unlimited access to water. The urine osmolality is less than 300 mOsm/kg. A urine specific gravity in the isosthenuric range (i.e., 1.008 to 1.015) does not rule out diabetes insipidus (Fig. 49-1), especially if the urine has been obtained after water is knowingly or inadvertently withheld (e.g., a long car ride and wait in the veterinary office). The urine of dogs and cats with partial diabetes insipidus can be concentrated into the isosthenuric range if they are dehydrated. Erythrocytosis (packed cell volume of 50% to 60%), hyperproteinemia, hypernatremia, and azotemia may be found in animals if their access to water has been restricted.

Diagnostic tests to confirm and differentiate among CDI, primary NDI, and psychogenic water consumption include the modified water deprivation test, random plasma osmolality determination, and the response to AVP supplementation. The results of these tests can be interpreted only after

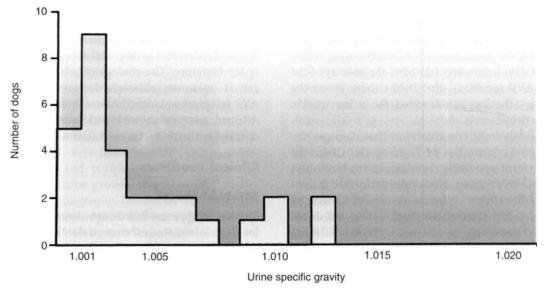

FIG 49-1
Urine specific gravity measured in 30 dogs with central diabetes insipidus at the time of initial presentation to the veterinarian. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

699

the causes for acquired secondary NDI have been ruled out.

#### MODIFIED WATER DEPRIVATION TEST

The technique, interpretation, contraindications, and complications of the modified water deprivation test are described in Chapter 42. The test consists of two phases. In phase I the AVP secretory capabilities and renal distal and collecting tubule responsiveness to AVP are evaluated by assessing the effects of dehydration (i.e., water restriction until the animal loses 3% to 5% of its body weight) on urine specific gravity. The normal dog and cat, as well as those with psychogenic water consumption, should be able to concentrate urine to greater than 1.030 (1.035 in the cat) if dehydrated. Dogs and cats with partial and complete CDI and primary NDI have an impaired ability to concentrate urine in the face of dehydration (Table 49-3 and Fig. 49-2). The time required to attain 3% to 5% dehydration can sometimes be helpful in establishing the diagnosis. It often takes less than 6 hours for dogs and cats with complete CDI to attain 3% to 5% dehydration, whereas it often takes more than 8 to 10 hours for dogs and cats with partial CDI, and especially those with psychogenic water consumption, to attain 3% to 5% dehydration.

Phase II of the water deprivation test is indicated for dogs and cats that do not concentrate urine to greater than 1.030 during phase I of the test. Phase II determines the effect, if any, that exogenous AVP has on the renal tubular ability to concentrate urine in the face of dehydration (see Fig. 49-2). This phase differentiates impaired AVP secretion from impaired renal tubular responsiveness to AVP (see Table 49-3).

# **RESPONSE TO DESMOPRESSIN (dDAVP)**

An alternative approach to establishing the diagnosis is to evaluate the animal's response to trial therapy with dDAVP (desmopressin acetate, Aventis Pharmaceuticals). One 0.1-mg or one-half of a 0.2-mg (dog) and one-half of a 0.1-mg (cat) dDAVP tablet is administered orally every 8 hours, or 1 to 4 drops of dDAVP nasal spray is administered from an eye dropper into the conjunctival sac every 12 hours for 5 to 7 days. The effect of dDAVP should not be critically evaluated until after 5 to 7 days of therapy because renal medul-

lary solute washout may prevent a dog or cat with CDI from forming concentrated urine in response to only one or two administrations. Clients should notice a decrease in PU and PD by the end of the treatment period if the PU and PD are caused by CDI. Urine specific gravity should be measured

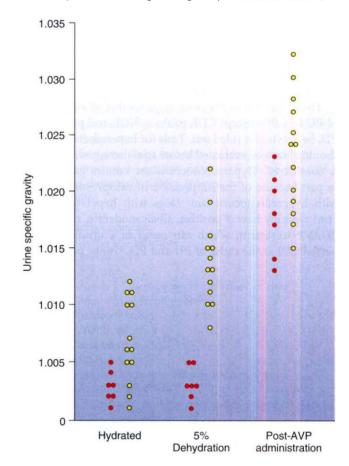

FIG 49-2

Urine specific gravity in seven dogs with complete central diabetes insipidus (red circle) and 13 dogs with partial central diabetes insipidus (yellow circle) at the beginning (hydrated), end of phase I (5% hydrated), and end of phase II (after arginine vasopressin administration) of the modified water deprivation test. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

TABLE 49-3

Guidelines for Interpretation of the Modified Water Deprivation Test

	URINE SPECIFIC GRAVITY			TIME TO 5% DEHYDRATION	
DISORDER	INITIALLY	5% DEHYDRATION	POST ADH	MEAN (hr)	RANGE (hr)
Central DI					
Complete	<1.006	<1.006	>1.008	4	3-7
Partial	<1.006	1.008-1.020	>1.015	8	6-11
Primary nephrogenic DI	<1.006	<1.006	<1.006	5	3-9
Primary polydipsia	1.002-1.020	>1.030	NA	13	8-20

on several urine samples collected by the client on the last couple of days of trial therapy. An increase in urine specific gravity by 50% or more, compared with pretreatment specific gravities, supports the diagnosis of CDI, especially if the urine specific gravity exceeds 1.030. There should be only minimal improvement in dogs and cats with primary NDI, although a response may be observed with very high doses of dDAVP. Dogs and cats with psychogenic water consumption may exhibit a mild decline in urine output and water intake because the chronically low serum osmolality tends to depress AVP production.

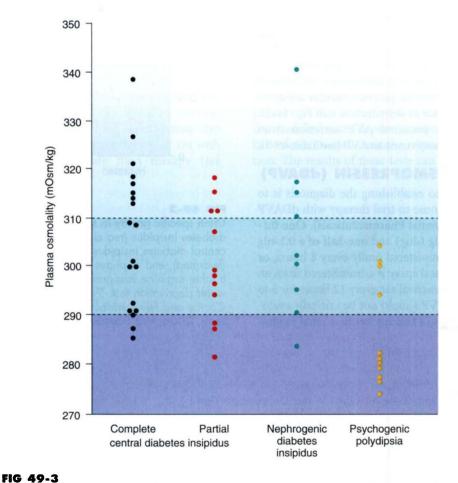

This approach to diagnosis requires that all other causes of PU and PD, except CDI, primary NDI, and psychogenic PD, be previously ruled out. Tests for hyperadrenocorticism should always be evaluated before trial therapy with dDAVP is considered. Hyperadrenocorticism mimics partial CDI, in part because of the suppression of vasopressin secretion with hyperadrenocorticism. Dogs with hyperadrenocorticism typically have a positive, albeit moderate, response to dDAVP treatment, which can result in a misdiagnosis of partial CDI as the cause of PU and PD. Unlike partial CDI,

the beneficial response to dDAVP wanes over the ensuing weeks in dogs with hyperadrenocorticism.

Although less time-consuming than the water deprivation test, the expense is often comparable, in part because of the cost of the dDAVP. In addition, the modified water deprivation test may still have to be performed if ambiguous results are obtained using this simpler approach.

#### RANDOM PLASMA OSMOLALITY

Measurement of random plasma osmolality may help identify primary or psychogenic PD. Plasma osmolality in normal dogs and cats is approximately 280 to 310 mOsm/kg. Diabetes insipidus is a primary polyuric disorder, with compensatory PD to prevent severe hyperosmolality. Random plasma osmolality should be greater than 300 mOsm/kg. Psychogenic PD is a primary polydipsic disorder, with compensatory PU to prevent hyposmolality and water intoxication. Random plasma osmolality should be less than 280 mOsm/kg. Unfortunately, there is considerable overlap in random plasma osmolality in animals with these disorders (Fig. 49-3). A random plasma osmolality of less than 280 mOsm/kg

Random plasma osmolality in 19 dogs with complete central diabetes insipidus, 12 dogs with partial central diabetes insipidus, 9 dogs with primary nephrogenic diabetes insipidus, and 11 dogs with primary (psychogenic) polydipsia. Note the overlap in values between groups of dogs. *Dashed lines*, Upper and lower limits for normal plasma

osmolality. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

obtained while the dog or cat has free access to water suggests the presence of psychogenic PD, whereas a plasma osmolality greater than 280 mOsm/kg is consistent with CDI, NDI, or psychogenic PD.

# **ADDITIONAL DIAGNOSTIC TESTS**

Neoplasia in the region of the pituitary and hypothalamus should be considered in the older dog or cat in which CDI develops. A complete neurologic evaluation, including computed tomographic (CT) or magnetic resonance (MR) scan may be warranted before idiopathic CDI is arbitrarily diagnosed, especially if the client is willing to consider radiotherapy or chemotherapy should a tumor be identified. Similarly, a more complete evaluation of the kidney (e.g., creatinine clearance studies, intravenous pyelogram, CT or MR scan, renal biopsy) may be warranted in the older dog or cat tentatively considered to have primary NDI.

# **Treatment**

Therapeutic options for dogs and cats with diabetes insipidus are listed in Box 49-2. The synthetic analog of vasopressin, dDAVP, is the standard therapy for CDI. dDAVP has almost three times the antidiuretic action of AVP, with minimal-to-no vasopressor or oxytocic activity. The intranasal dDAVP preparation (dDAVP nasal drops, 2.5- and 5.0-ml bottles containing 100 µg dDAVP/ml) is used most commonly for treating CDI in dogs and cats. Administration of medication to animals via the intranasal route is possible but not recommended. The dDAVP nasal preparation may be transferred to a sterile eye dropper bottle and drops placed into the conjunctival sac of the dog or cat. Although the solution is acidic, ocular irritation rarely occurs. One drop of dDAVP contains 1.5 to 4 µg of dDAVP, and a dosage of one to four drops administered once or twice daily controls signs of CDI in most animals.

Oral dDAVP (dDAVP tablets, 0.1 and 0.2 mg) can be used to treat CDI, although the clinical response is variable. The bioavailability of oral dDAVP is approximately 5% to 15% of the intranasal dose in humans. Similar information is not available for dogs and cats. The initial oral dDAVP dose is 0.1 mg (dogs) and 0.05 mg (cats) given three times a day. The dose is gradually increased to effect if unacceptable PU and PD persist 1 week after therapy is initiated. Decreasing the frequency of administration to twice a day, decreasing the dose of dDAVP, or both can be tried once clinical response has been documented. To date, most dogs have required 0.1 to 0.2 mg of dDAVP two to three times a day, and most cats have required 0.025 to 0.05 mg of dDAVP two to three times a day to control PU and PD. Treatment should be switched to the intranasal dDAVP preparation if there is minimal to no response to 0.2 mg (dog) or 0.05 mg (cat) of oral dDAVP administered three times a day.

The maximal effect of dDAVP, regardless of the route of administration, occurs from 2 to 8 hours after administration, and the duration of action varies from 8 to 24 hours. Larger doses of dDAVP appear both to increase its antidiuretic effects and to prolong its duration of action; however,

BOX 49-2

Therapies Available for Polydipsic/Polyuric Dogs and Cats with Central Diabetes Insipidus, Nephrogenic Diabetes Insipidus, or Primary (Psychogenic) Polydipsia

- A. Central diabetes insipidus (severe)
  - 1. dDAVP (desmopressin acetate)
    - a. Effective
    - b. Expensive
    - C. Oral tablets or drops of nasal solution in conjunctival sac
  - 2. LVP (lypressin [Diapid])
    - a. Short duration of action; less potent than dDAVP
    - b. Expensive
    - c. Requires drops into nose or conjunctival sac
  - 3. No treatment-provide continuous source of water
- B. Central diabetes insipidus (partial)
  - dDAVP
  - LVP
  - 3. Chlorpropamide
    - a. 30%-70% effective
    - b. Inexpensive
    - c. Pill form
    - d. Takes 1-2 weeks to obtain effect of drug
    - e. May cause hypoglycemia
  - 4. Thiazide diuretics
    - a. Mildly effective
    - b. Inexpensive
    - c. Pill form
    - d. Should be used with low-sodium diet
  - 5. Low-sodium diet (NaCl < 0.9 g/1000 kcal/ME)
  - 6. No treatment-provide continuous source of water
- C. Nephrogenic diabetes insipidus
  - 1. Thiazide diuretics
  - 2. Low-sodium diet (NaCl < 0.9 g/1000 kcal/ME)
  - 3. No treatment-provide continuous source of water
- D. Primary (psychogenic) polydipsia
  - 1. Water restriction at times
  - 2. Water limitation
  - 3. Change in environment or daily routine; excercise; increased contact with humans or dogs

ME, Metabolizable energy

expense becomes a limiting factor. The medication may be administered exclusively in the evening as insurance against nocturia.

Chlorpropamide, thiazide diuretics, and oral sodium chloride restriction have a limited efficacy in the treatment of NDI. dDAVP may control the clinical signs if administered in massive amounts (i.e., five to ten times the amount used for the treatment of CDI), but the cost of the drug obviously detracts from the attractiveness of this therapeutic approach. Fortunately, therapy for CDI or NDI is not mandatory as long as the dog or cat has unlimited access to water and is housed in an environment that cannot be damaged by severe PU. A constant water supply is of paramount importance because relatively short periods of water restric-

tion can have catastrophic results (i.e., the development of hypernatremic, hypertonic dehydration and neurologic signs).

# **Prognosis**

Dogs and cats with idiopathic or congenital CDI become relatively asymptomatic in response to appropriate therapy, and with proper care these animals have an excellent life expectancy. PU and PD frequently resolve in dogs and cats with trauma-induced CDI, often within 2 weeks of the traumatic incident. The prognosis in dogs and cats with hypothalamic and pituitary tumors is guarded to grave. Neurologic signs typically develop within 6 months after the diagnosis of CDI, and clinical response to radiotherapy and chemotherapy is variable and unpredictable.

The prognosis for animals with primary NDI is guarded to poor because of limited therapeutic options and the generally poor response to therapy. The prognosis for animals with secondary NDI depends on the prognosis of the primary problem.

# PRIMARY (PSYCHOGENIC) POLYDIPSIA

Primary PD is defined as a marked increase in water intake that cannot be explained as a compensatory mechanism for excessive fluid loss. In humans primary PD results from a defect in the thirst center or may be associated with mental illness. Primary dysfunction of the thirst center resulting in compulsive water consumption has not been reported in the dog or cat, although an abnormal vasopressin response to hypertonic saline infusion has been reported in dogs with suspected primary PD. A psychogenic or behavioral basis for compulsive water consumption does occur in the dog but has not been reported in the cat. Psychogenic PD may be induced by concurrent disease (e.g., hepatic insufficiency, hyperthyroidism) or may represent a learned behavior following a change in the pet's environment. PU is compensatory to prevent overhydration.

Dogs (and presumably cats) with primary or psychogenic PD have an intact hypothalamic-pituitary-renal axis for controlling fluid balance and variable severity of renal medullary solute washout. Because AVP production and renal tubular response to AVP are normal, these dogs can concentrate urine in excess of 1.030. Depending on the severity of renal medullary solute washout, a period of 24 hours or longer of water deprivation may be necessary to attain concentrated urine. Psychogenic PD is diagnosed by exclusion of other causes of PU and PD and by demonstrating that the dog or cat can concentrate urine to a specific gravity in excess of 1.030 during water deprivation.

Treatment is aimed at gradually limiting water intake to amounts in the high-normal range. The client should determine the dog's approximate water intake in a 24-hour period when free-choice water is allowed, and this volume of water is then reduced by 10% per week until water volumes of 60 to 80 ml/kg/24 h are reached. The total 24-hour volume of

water should be divided into several aliquots, with the last aliquot given at bedtime. Oral salt (1 g/30 kg q12h) and/or oral sodium bicarbonate (0.6 g/30 kg q12h) may also be administered for 3 to 5 days to help reestablish the renal medullary concentration gradient. Changes in the dog's environment or daily routine should be considered, such as initiating a daily exercise routine; bringing a second pet into the home; providing some distraction, such as a radio playing when the clients are not home; or moving the dog to an area with an increased amount of contact with humans.

# **ENDOCRINE ALOPECIA**

Symmetric alopecia without historical or clinical evidence of inflammation usually results from hair cycle arrest induced by hormonal diseases—hence the term *endocrine alopecia* (Fig. 49-4). Hair follicles are atrophic, hairs are easily epilated, the skin is often thin and hypotonic, and hyperpigmentation is common. Other dermatologic lesions, such as scales, crusts, and papules, are absent. Seborrhea and pyoderma may develop, depending on the underlying cause.

Causes of endocrine alopecia are listed in Table 49-4. In dogs the most common causes are hypothyroidism and glucocorticoid excess (iatrogenic or spontaneous). Feline endocrine alopecia is perhaps the most common endocrine alopecia in cats. The diagnostic evaluation for endocrine alopecia begins with a complete history, physical examination, and routine blood and urine tests, (i.e., CBC, serum biochemistry panel, and urinalysis). Results of these tests will often provide evidence for hypothyroidism and hyperadrenocorticism, and appropriate diagnostic tests can then be performed to confirm these diagnoses (see Chapters 51 and 53, respectively).

FIG 40.4

Endocrine alopecia, thin skin, and severe obesity in a 7-year-old male castrated Pomeranian with iatrogenic hyperadrenocorticism caused by chronic administration of prednisone for a seizure disorder. Note the symmetric truncal alopecia with sparing of the head and distal extremities.

# Disorders Causing Endocrine Alopecia

DISORDER	COMMON CLINICOPATHOLOGIC ABNORMALITIES	DIAGNOSTIC TESTS
Hypothyroidism	Lipemia, hypercholesterolemia, mild nonregenerative anemia	Serum T <sub>4</sub> , free T <sub>4</sub> , TSH concentrations
Hyperadrenocorticism	Stress leukogram, increased ALP, hypercholesterolemia, hyposthenuria, proteinuria, urinary tract infection	Urine cortisol/creatinine ratio, low-dose dexamethasone suppression test, abdominal US
Hyperestrogenism	, , , , , , , , , , , , , , , , , , , ,	
Functional Sertoli cell tumor in male dog	None (bone marrow depression uncommon)	Physical findings, abdominal US, cytologic or histopathologic findings, plasma estrogen concentration
Hyperestrogenism in intact female dog	None (bone marrow depression uncommon)	Vaginal cytology, abdominal US, plasma estrogen concentration, response to ovariohysterectomy
Hyperprogesteronism	None	Physical findings, abdominal US, serum progesterone concentration
Increased adrenocortical steroid hormone intermediates (adrenal hyperplasia-like syndrome, Alopecia-X)	None	Measure adrenocortical steroid hormone intermediates before and after ACTH administration
Growth hormone deficiency pituitary dwarfism	None	Signalment, physical findings, growth hormone response test
Growth hormone-responsive dermatosis—adult dog	None	Growth hormone response test, response to growth hormone replacement therapy
Castration-responsive dermatosis Hypoestrogenism (?)	None	Response to castration
Estrogen-responsive dermatosis of spayed female dogs Hypoandrogenism (?)	None	Response to estrogen therapy
Testosterone-responsive dermatosis—male dog	None	Response to testosterone therapy
Feline endocrine alopecia	None	Response to progestin therapy
Telogen defluxion (effluvium)	None	History of recent pregnancy or diestrus
Diabetes mellitus	Hyperglycemia, glycosuria	Blood and urine glucose measurement

T<sub>4</sub>, Tetraiodothyronine; TSH, thyroid-stimulating hormone; ALP, alkaline phosphatase; US, ultrasonography; ACTH, adrenocorticotropic hormone.

Once hypothyroidism and hyperadrenocorticism have been ruled out, the next diagnostic step is to rule out an excess of one of the sex hormones or one of the adrenocortical steroid hormone intermediates. Dermatologic manifestations are similar for most sex hormone—induced dermatoses and include endocrine alopecia that initially begins in the perineal, genital, and ventral abdominal regions and spreads cranially; dull, dry, easily epilated hair; failure of the haircoat to regrow after clipping; and variable presence of seborrhea and hyperpigmentation. Additional clinical signs of hyperestrogenism may include gynecomastia, a pendulous prepuce, the attraction of other male dogs, squatting to urinate, and unilateral testicular atrophy (contralateral to the testicular tumor) in the male dog and vulvar enlargement and persistent proestrus or estrus in the bitch. Results

of a CBC may reveal aplastic anemia. Histologic assessment of a skin biopsy specimen can be used to identify nonspecific endocrine-related alterations and support the diagnosis of endocrine alopecia (Table 49-5). There are no pathognomonic histologic changes for sex hormone—induced dermatoses. The identification of an increased plasma estrogen (i.e., estradiol) concentration would support the presence of a functional Sertoli cell tumor in the dog and hyperestrogenism in the bitch (assuming that the bitch is not in proestrus or early estrus). Abdominal ultrasound may identify ovarian cysts or neoplasia in the bitch with hyperestrogenism, and abdominal and testicular ultrasound may identify testicular neoplasia in the male dog. Hyperestrogenism and endocrine alopecia will resolve after surgical removal of the ovarian cyst, ovarian tumor, or testicular tumor.

# **TABLE 49-5**

# Dermatohistopathologic Alterations Associated with Endocrinopathy-Induced Alopecia

ABNORMALITY	SPECIFIC ENDOCRINE DISORDER
Nonspecific Abnormalities Supporting an Endocrinopathy	
Orthokeratotic hyperkeratosis	
Follicular keratosis	
Follicular dilatation	
Follicular atrophy	
Predominance of telogen hair follicles	
Sebaceous gland atrophy	The property of the property o
Epidermal atrophy	
Epidermal melanosis	And the second of the second o
Thin dermis	
Dermal collagen atrophy	THE STATE OF THE S
Abnormalities Suggestive of Specific Endocrine Disorder	
Decreased amount and size of dermal elastin fibers	Hyposomatotropism
Excessive trichilemmal keratinization (flame follicles)	Growth hormone- and castration-responsive dermatosis
Vacuolated and/or hypertrophied arrector pilae muscles	Hypothyroidism
Increased dermal mucin content	Hypothyroidism
Thick dermis	Hypothyroidism
Comedones	Hyperadrenocorticism
Calcinosis cutis	Hyperadrenocorticism
Absence of arrector pilae muscles	Hyperadrenocorticism

An abnormal increase in serum progesterone may result from adrenocortical neoplasia, functional ovarian luteal cysts in the bitch, and as a component of an imbalance in adrenocortical steroid hormone intermediates. Functional luteal cysts may cause prolonged anestrus or failure to cycle in the bitch. Clinical features of progesterone-secreting adrenocortical tumors mimic hyperadrenocorticism (see Chapter 53). Documenting increased serum progesterone concentration establishes the diagnosis, especially in a male or female spayed animal. Serum progesterone is normally increased in an intact female dog or cat in diestrus. A history of recent cycling behavior and examination of the ovaries and adrenal glands with abdominal ultrasound will help differentiate diestrus, functional luteal cysts, and adrenal neoplasia.

An increase in one or more of the adrenocortical steroid hormone intermediates often occurs in association with pituitary-dependent and adrenocortical tumor—dependent hyperadrenocorticism (Fig. 49-5). The predominant clinical signs in these dogs result from an excess of cortisol. An imbalance of adrenocortical steroid hormone intermediates such as 17-hydroxyprogesterone, progesterone, and androstenedione has been proposed as an explanation for hair cycle arrest, endocrine alopecia, and hyperpigmentation in dogs that do not have hyperadrenocorticism. A partial deficiency of 21-hydroxylase enzyme may account for the clinical and hormonal findings. Clinical signs for this syndrome (referred to as *adrenal hyperplasia-like syndrome* or *Alopecia-X*) are characterized by hair cycle arrest; bilaterally symmetric, nonpruritic alopecia; and hyperpigmentation of

FIG 49-5
A 7-year-old Poodle mix with hyperadrenocorticism and an increase in adrenocortical steroid hormone intermediates. Clinical signs included polyuria, polydipsia, and thinning of the haircoat on the trunk and tail. Tests of the pituitary-adrenocortical axis were inconclusive, and serum 17-hydroxyprogesterone concentrations were increased.

the skin and have been identified in many breeds, most notably in the American Eskimo, Pomeranian, Chow Chow, Keeshond, Malamute, Poodle, Samoyed, and Siberian Husky (Frank et al., 2003). Males are overrepresented. Routine blood and urine test results are typically normal. Skin biopsies from affected dogs show the typical changes of endo-

crine alopecia (see Table 49-5) and may also show features of follicular dysplasia. Diagnosis requires evaluation of adrenocortical steroid hormone intermediates and sex hormones before and after adrenocorticotropic hormone (ACTH) administration (see Chapter 53). The most common abnormality is an increase in serum 17-hydroxyprogesterone concentration. Currently, the only laboratory with established normal values for intermediate and sex steroids is the Endocrinology Laboratory at the University of Tennessee, College of Veterinary Medicine, Knoxville, TN 37901-1071. Treatment has included trilostane and mitotane.

The differential diagnoses become more nebulous and the ability to establish a definitive cause of the alopecia more difficult once hypothyroidism, hyperadrenocorticism, and increased sex hormone and/or adrenocortical steroid hormone intermediates have been ruled out. Clinical manifestations of growth hormone (GH)-responsive dermatosis are similar to those described for increased adrenocortical steroid hormone intermediates (Fig. 49-6). Commonly affected breeds include Chow Chows, Pomeranians, Toy and Miniature Poodles, Keeshonds, American Water Spaniels, and Samoyeds; males are overrepresented; routine blood and urine test results are normal; and the endocrine alopecia responds to GH treatment. Unfortunately, there is no commercially available assay for measuring GH in dogs, and an effective GH product for treatment is not available for dogs.

Endocrine alopecia may result from a deficiency of one of the sex hormones, most notably estrogens or androgens, or may be responsive to treatment with one of the sex hormones (see Table 49-4). Dermatologic manifestations are similar for most sex hormone-induced and sex hormoneresponsive dermatoses and mimic the syndrome induced by alterations in sex hormone and adrenocortical steroid hormone intermediates (adrenal hyperplasia-like syndrome, Alopecia-X) and GH-responsive dermatosis, creating a difficult diagnostic challenge for the veterinarian, especially when the alopecia occurs in a breed such as the Chow Chow or Pomeranian. Diagnosis of sex hormone-deficiency or sex hormone-responsive dermatosis is based on response to treatment (Table 49-6). Castration of intact male dogs or sex hormone replacement therapy (e.g., diethylstilbestrol, methyltestosterone) in previously castrated or spayed dogs can be considered in dogs with endocrine alopecia of undetermined cause. Because of potentially serious adverse reactions to sex hormone replacement therapy, the more common causes of endocrine alopecia should always be ruled out before initiating treatment. The haircoat should improve within 3 months of the start of therapy. If there is no improvement within this time, another diagnosis should be considered.

Response to melatonin treatment (3 to 6 mg q12-24h for 6 weeks) is perhaps the most innocuous nonspecific treatment option if diagnostic options have been exhausted and

A and B, Endocrine alopecia in a 6-year-old Pomeranian with suspected adult-onset, GH-responsive dermatosis. Note the symmetric truncal alopecia with lesser involvement of the extremities and sparing of the head.

TABLE 49-6

Treatment for Sex Hormone-Induced or Sex Hormone-Responsive Endocrine Alopecia

DISORDER	PRIMARY TREATMENT	POTENTIAL ADVERSE REACTIONS TO THERAPY
Sertoli cell neoplasia	Castration	None
Castration-responsive dermatosis	Castration	None
Hyperestrogenism in the intact female dog	Ovariohysterectomy	None
Estrogen-responsive dermatosis of spayed female dogs	Diethylstilbestrol, 0.1-1.0 mg PO q24h 3 weeks per month; once responds, 0.1-1 mg q4-7 days	Aplastic anemia
Feline endocrine alopecia	Megestrol acetate, 2.5-5 mg/cat q48h until hair regrows; then 2.5-5 mg/cat q7-14 days	Adrenocortical suppression, benign mammary hypertrophy, mammary neoplasia, pyometra (female cats); infertility (male cats), diabetes mellitus
Testosterone-responsive dermatosis	Methyltestosterone, 1 mg/kg (maximum 30 mg) PO q48h until hair regrows, then q4-7 days	Aggression, hepatopathy
Telogen defluxion (effluvium)	None	None
Adrenal hyperplasia-like syndrome, Alopecia-X	Mitotane, trilostane Melatonin (see Chapter 53)	Hypoadrenocorticism

PO, By mouth.

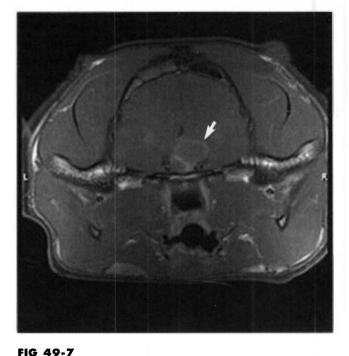

a definitive diagnosis for the endocrine alopecia has not been established. The mechanism of action of melatonin for promoting hair growth is not clear. Proposed mechanisms of action include inhibition of gonadotropin-releasing hormone (GnRH) secretion, thereby decreasing follicle-stimulating hormone (FSH), luteinizing hormone (LH), and sex hormone concentrations; stimulation of prolactin secretion; stimulation of GH or insulin-like growth factor-I (IGF-I) secretion; and a direct effect on hair follicles.

Many clients elect not to treat their dog once hypothyroidism, hyperadrenocorticism, ovarian cysts, and neoplasia of the adrenal gland, ovary, and testis have been ruled out. For these dogs the long-term prognosis is good, even without treatment. Dogs remain healthy aside from the alopecia and hyperpigmentation.

# FELINE ACROMEGALY

#### Etiology

Chronic excessive secretion of GH in adult cats results in acromegaly, a disease characterized by overgrowth of connective tissue, bone, and viscera. In cats acromegaly is caused by a functional adenoma of the somatotropic cells of the pituitary pars distalis that secretes excess GH (Fig. 49-7). In most cats the pituitary tumor is a macroadenoma that extends dorsally above the sella turcica. Progestogen-induced acromegaly has not been documented in the cat. Progestogens, including megestrol acetate, do not appear to stimulate GH or IGF-I secretion in the cat. In contrast, acromegaly in the dog is seen most commonly after prolonged exposure to progestogens, either exogenously administered (e.g.,

Magnetic resonance image of the pituitary region of a 6-yearold male, castrated domestic short-haired cat with insulinresistant diabetes mellitus and acromegaly (see Fig. 49-8, A). A mass is evident in the hypothalamic-pituitary region (arrow).

medroxyprogesterone acetate) or late in life after years of endogenous progesterone secretion during the diestrual phase of the estrous cycle in the intact bitch.

Chronic excess secretion of GH has catabolic and anabolic effects. The anabolic effects are caused by increased concentrations of IGF-I. The growth-promoting effects of IGF-I result in proliferation of bone, cartilage, and soft tissues and in organomegaly, most notably of the kidney and heart. These anabolic effects are responsible for producing the classic clinical manifestations of acromegaly (Box 49-3). The catabolic effects of GH are a direct result of GH-induced insulin resistance that ultimately results in carbohydrate intolerance, hyperglycemia, and the development of diabetes mellitus that quickly becomes resistant to insulin treatment. Most but not all cats with acromegaly have diabetes mellitus at the time acromegaly is diagnosed, and most eventually develop severe resistance to exogenously administered insulin.

#### **Clinical Features**

Acromegaly typically occurs in male, mixed-breed cats that are 8 years of age or older. Clinical signs result from the catabolic, diabetogenic effects of GH, the anabolic actions of chronic IGF-I secretion by the liver, and growth of the pituitary macroadenoma (see Box 49-3). The earliest clinical signs are usually PU, PD, and polyphagia resulting from concurrent diabetes mellitus. Polyphagia can become quite intense. Weight loss varies and depends in part on whether the anabolic effects of IGF-I or the catabolic effects of uncontrolled diabetes predominate. Most cats initially lose weight and then experience a period of stabilization followed by a slow, progressive gain in body weight as the anabolic effects of IGF-I begin to dominate the clinical picture. Severe insulin resistance eventually develops. Insulin dosages in cats with acromegaly frequently exceed 2 to 3 U/kg of body weight twice a day, with no apparent decline in the blood glucose concentration.

Clinical signs related to the anabolic actions of excess GH secretion (see Box 49-3) may be evident at the time diabetes mellitus is diagnosed. More commonly, however, they become apparent several months after diabetes has been diagnosed, often in conjunction with the realization that hyperglycemia is difficult to control with exogenous insulin therapy. Because of the insidious onset and slowly progressive nature of the anabolic clinical signs, clients are often not aware of the subtle changes in the appearance of their cat until the clinical signs are quite obvious. Anabolic changes in acromegalic cats include an increase in body size, enlargement of the abdomen and head, development of prognathia inferior, and weight gain (Fig. 49-8). Weight gain in a cat with poorly regulated diabetes mellitus is an important diagnostic clue to acromegaly. With time, organomegaly, especially of the heart, kidney, liver, and adrenal gland, develop. Diffuse thickening of soft tissues in the pharyngeal region can lead to extrathoracic upper airway obstruction and respiratory distress.

Neurologic signs may develop as a result of pituitary tumor growth and the resultant invasion and compression of the hypothalamus and thalamus. Signs include stupor, somnolence, adipsia, anorexia, temperature deregulation, circling, seizures, and changes in behavior. Blindness is not common because the optic chiasm is located anterior to the

pituitary gland. Papilledema may be evident during an ophthalmic examination. Peripheral neuropathy causing weakness, ataxia, and a plantigrade stance may develop as a result of poorly controlled diabetes mellitus. Other endocrine and metabolic abnormalities resulting from the compressive effects of the tumor on the pituitary are uncommon.

#### FIG 49-8

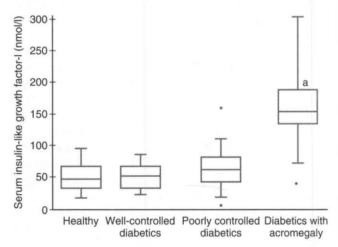

**A**, A 6-year-old male, castrated domestic short-haired cat with insulin-resistant diabetes mellitus and acromegaly. Note the broad face and mildly protruding mandible (prognathia inferior). **B** and **C**, An 8-year-old male, castrated domestic short-haired cat with insulin-resistant diabetes mellitus and acromegaly. Note the broad head, mildly protruding mandible, and prognathia inferior with displacement of the lower canine teeth. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

# **Clinical Pathology**

Concurrent, poorly controlled diabetes mellitus is responsible for causing most of the abnormalities identified on a serum biochemistry panel and urinalysis, including hyperglycemia, glycosuria, hypercholesterolemia, and a mild increase in alanine transaminase and alkaline phosphatase activities. Ketonuria is an infrequent finding. Mild erythrocytosis, persistent mild hyperphosphatemia without concurrent azotemia, and persistent hyperproteinemia (total serum protein concentration of 8.2 to 9.7 mg/dl) with a normal pattern of distribution on protein electrophoretic studies may also be found. Renal failure is a potential sequela of acromegaly and, if present, will be associated with azotemia, isosthenuria, and proteinuria.

# **Diagnosis**

Clinical suspicion for acromegaly is based on the identification of conformational alterations (e.g., increased body size, large head, prognathia inferior, organomegaly) associated with acromegaly and a stable or progressive increase in body weight in a cat with insulin-resistant diabetes mellitus. Measurement of serum IGF-I concentration provides further evidence for the diagnosis of acromegaly. Measurement of serum IGF-I is commercially available (e.g., Diagnostic Endocrinology Laboratory, College of Veterinary Medicine, Michigan State University, East Lansing, MI 48909-7576). Concentrations are usually increased in acromegalic cats, but values may be in the reference range in the early stages of the disease (Fig. 49-9). Repeat measurements

# FIG 49-9

Box plots of serum concentrations of insulin-like growth factor-I (IGF-I) in 38 healthy cats, 15 well-controlled diabetic cats, 40 poorly controlled diabetic cats, and 19 poorly controlled diabetic cats with acromegaly. For each box plot, T-bars represent the main body of data, which in most instances is equal to the range. Each box represents the interquartile range (twenty-fifth to seventy-fifth percentile). The horizontal bar in each box is the median. Asterisks represent outlying data points. (a) P < 0.0001, compared with healthy cats and well-controlled and poorly controlled diabetic cats. (From Berg RIM et al: Serum insulin-like growth factor-I concentration in cats with diabetes mellitus and acromegaly, J Vet Intern Med 21:892, 2007.)

performed 4 to 6 months later will usually demonstrate an increase in serum IGF-I if acromegaly is present. The increase in serum IGF-I typically coincides with development and growth of the pituitary somatotropic adenoma. Increased serum IGF-I concentrations have been identified in a small number of poorly controlled diabetic cats in which the poor control was not caused by acromegaly. Interpretation of serum IGF-I test results should always take into consideration the status of control of the diabetic state, the presence and severity of insulin resistance, and the index of suspicion for acromegaly based on review of the history, physical examination, and results of routine blood and urine tests and diagnostic imaging. Identifying an increased serum IGF-I concentration in a poorly controlled diabetic cat with insulin resistance and clinical features suggestive of acromegaly supports the diagnosis and provides justification for CT or MR imaging of the pituitary gland. Documenting a pituitary mass by CT or MR scanning (see Fig. 49-7) adds further evidence for the diagnosis and is indicated whenever the client is considering radiation treatment. It is usually necessary to administer a positive contrast agent to visualize a pituitary mass using CT or MR imaging.

A definitive diagnosis of acromegaly requires documentation of an increased baseline serum GH concentration. Baseline serum GH concentration in cats with acromegaly typically exceeds 10 ng/ml (normal concentration is less than 5 ng/ml). Unfortunately, a commercial GH assay is not available for cats.

# ACROMEGALY VERSUS HYPERADRENOCORTICISM

Hyperadrenocorticism and acromegaly are uncommon disorders that occur in older cats, have a strong association with diabetes mellitus, can cause severe insulin resistance, and are often caused by a functional pituitary macrotumor. Clinical signs related to poorly controlled diabetes mellitus are common in cats with hyperadrenocorticism and acromegaly. Additional clinical signs differ dramatically between these two disorders. Hyperadrenocorticism is a debilitating disease that results in progressive weight loss leading to cachexia and dermal and epidermal atrophy leading to extremely fragile, thin, easily torn and ulcerated skin (i.e., feline fragile skin syndrome). In contrast, conformational changes caused by the anabolic actions of chronic IGF-I secretion dominate the clinical picture in acromegaly, most notably an increase in body size, prognathia inferior, and weight gain despite poorly regulated diabetes mellitus. Feline fragile skin syndrome does not occur with acromegaly. With both disorders most of the abnormalities identified on routine blood and urine tests are caused by concurrent poorly controlled diabetes mellitus. Abdominal ultrasound may also reveal mild bilateral adrenomegaly with both disorders. Ultimately, the differentiation between the two diseases is based on results of tests of the pituitaryadrenocortical axis (see Chapter 53) and serum GH and/or IGF-1 concentrations.

# **Treatment**

Radiotherapy is currently considered the most viable treatment option for acromegaly in cats. Cobalt teletherapy involves the administration of a total dose of 45 to 48 Gy in daily fractions five days per week for 3 to 4 weeks. The clinical response to cobalt teletherapy is unpredictable and ranges from no response to a dramatic response, characterized by shrinkage of the tumor; elimination of hypersomatotropism; resolution of insulin resistance; and, in some cats, reversion to a subclinical diabetic state (see Fig. 49-7). Typically, tumor size and plasma GH and serum IGF-I concentrations decrease and insulin responsiveness improves after cobalt teletherapy, although this improvement may take 6 months or longer to occur after radiation treatment. In most treated cats that respond to radiation therapy, diabetes mellitus and/or insulin resistance recurs 6 months or longer after treatment, although growth of the pituitary mass is often not evident on CT or MR imaging.

Microsurgical transsphenoidal hypophysectomy has been shown to be effective for the treatment of feline pituitary-dependent hyperadrenocorticism, but use of this specialized surgical technique for the treatment of acromegaly has not been reported. Successful use of transsphenoidal cryotherapy of a pituitary tumor has been described in a cat with acromegaly. An effective medical treatment for acromegaly in cats has not been identified.

### **Prognosis**

The short- and long-term prognosis for cats with tumorinduced acromegaly is guarded to good and poor, respectively. The survival time has ranged from 4 to 60 months (typically 1.5 to 3 years) from the time the diagnosis of acromegaly is established. The GH-secreting pituitary tumor usually grows slowly, and neurologic signs associated with an expanding tumor are uncommon until late in the disorder. Diabetes mellitus is difficult to control, even with the administration of large doses of insulin (20 U or more/injection) given twice daily. Administration of large doses of insulin is not recommended. The severity of insulin resistance fluctuates unpredictably in cats with acromegaly, and severe, life-threatening hypoglycemia may suddenly develop after months of insulin resistance and blood glucose concentrations in excess of 400 mg/dl. To prevent severe hypoglycemia, insulin doses should not exceed 12 to 15 units per injection. Most cats with acromegaly eventually die or are euthanized because of the development of severe congestive heart failure, renal failure, respiratory distress, the neurologic signs of an expanding pituitary tumor, or coma caused by severe hypoglycemia.

# PITUITARY DWARFISM

## Etiology

Pituitary dwarfism results from a congenital deficiency of GH. Studies in German Shepherd Dog dwarfs suggest that congenital GH deficiency is caused by primary failure of differentiation of the craniopharyngeal ectoderm into normal tropic hormone-secreting pituitary cells. Pituitary cysts are commonly identified with diagnostic imaging of the pituitary region using CT or MR imaging and may enlarge as the pituitary dwarf ages. However, current belief is that pituitary cysts develop secondary to primary failure of anterior pituitary formation in most pituitary dwarfs. Pituitary dwarfism is encountered most often as a simple, autosomal recessive inherited abnormality in the German Shepherd Dog. A similar mode of inheritance has been reported in Carnelian Bear dogs. Inherited pituitary dwarfism may be due to isolated GH deficiency or may be part of a combined pituitary hormone deficiency. Concurrent deficiency in thyroid-stimulating hormone (TSH) and prolactin are most commonly identified in affected German Shepherd Dogs; ACTH secretion is preserved. Kooistra et al. (2000) hypothesize that the disorder is caused by a mutation in a developmental transcription factor that precludes effective expansion of a pituitary stem cell after differentiation of the corticotropic cells that produce ACTH. Pituitary dwarfism resulting from a mutant GH or an insensitivity to GH owing to a lack of or defect in GH receptors (e.g., Laron-type dwarfism in human beings) has not been documented in dogs or cats.

#### **Clinical Features**

#### **SIGNALMENT**

Pituitary dwarfism occurs primarily in German Shepherd Dogs, although pituitary dwarfism in other dog breeds, including the Weimaraner, Spitz, Miniature Pinscher, Carnelian Bear dog, and Labrador Retriever, and in cats has also been observed. There does not appear to be a sex-related predilection.

#### **CLINICAL SIGNS**

The most common clinical manifestations of pituitary dwarfism are lack of growth (i.e., short stature), endocrine alopecia, and hyperpigmentation of the skin (Box 49-4). Affected animals are usually normal in size during the first 2 to 4 months of life but after that grow more slowly than their litter mates. By 5 to 6 months of age, affected dogs and cats are obviously runts of the litter and do not attain full adult dimensions. Dwarfs with an isolated GH deficiency typically maintain a normal body contour and body proportions as they age (i.e., proportionate dwarfism), whereas dwarfs with combined deficiencies (most notably TSH) may acquire a square or chunky contour typically associated with congenital hypothyroidism (i.e., disproportionate dwarfism; Fig. 49-10).

The most notable dermatologic sign is retention of the lanugo or secondary hairs, with concurrent lack of the primary or guard hairs. As a result, the haircoat in a dwarf is initially soft and wooly. The lanugo hairs are easily epilated, and a bilateral symmetric alopecia gradually develops. Initially, hair loss is confined to areas of wear, such as the neck (collar) and posterolateral aspects of the thighs (from sitting). Eventually, the entire trunk, neck, and proximal limbs become alopecic, with primary hairs remaining only on the face and distal extremities. The skin is initially normal

but becomes hyperpigmented, thin, wrinkled, and scaly. Comedones, papules, and secondary pyoderma frequently develop in the adult dwarf. Secondary bacterial infections are common long-term complications.

Hypogonadism may also develop, although normal reproductive function has been observed in some animals with pituitary dwarfism. In the male animal cryptorchidism, testicular atrophy, azoospermia, and a flaccid penile sheath are typical; in the female persistent anestrus is common with impaired secretion of pituitary gonadotropins.

## Clinical Pathology

Results of a CBC, serum biochemical panel, and urinalysis are usually normal in animals with uncomplicated pituitary dwarfism and isolated GH deficiency. Concurrent deficiency of TSH may result in clinicopathologic abnormalities affiliated with hypothyroidism, such as hypercholesterolemia and anemia (see Chapter 51). Deficiency of GH, IGF-I, and TSH may also affect kidney development and function, resulting in azotemia.

<sup>\*</sup>Common finding.

#### FIG 49-10

**A,** A 9-month-old male domestic short-haired cat with pituitary dwarfism. The size of the pituitary dwarf cat was similar to that of an 8-week-old kitten. Note the normal body contour and juvenile appearance. **B** and **C,** A 7-month-old female German Shepherd Dog with pituitary dwarfism. Note the normal body contour, puppy haircoat, and juvenile appearance. **D,** A 2-year-old female spayed Labrador Retriever with pituitary dwarfism sitting next to an age-matched normal Labrador Retriever to illustrate the small stature and juvenile appearance of the pituitary dwarf. All of the pituitary dwarfs presented with the primary owner complaint of failure of their pet to grow.

# **Diagnosis**

The signalment, history, and physical examination usually provide sufficient evidence for pituitary dwarfism to be included among the tentative diagnoses of short stature. Strong presumptive evidence can be obtained by ruling out other potential causes of small size (Box 49-5) after a thor-

ough evaluation of the history and physical examination findings, results of routine laboratory studies (i.e., CBC, fecal examinations, serum biochemical panel, urinalysis), and radiographic studies (Fig. 49-11). Serum IGF-I concentrations are decreased in pituitary dwarfs. Because baseline plasma GH concentrations may be low in healthy dogs and

cats, a definitive diagnosis of hyposomatotropism requires evaluation of plasma GH concentrations during a stimulation test (Table 49-7). GH-releasing hormone (GHRH, 1  $\mu$ g/kg body weight), clonidine (10  $\mu$ g/kg), or xylazine (100  $\mu$ g/kg) can be used. Blood for plasma GH measurements should be obtained immediately before and 20 and 30 minutes after intravenous administration of the secretagogue. In pituitary dwarfs there is no increase in plasma GH concentration after the administration of a GH secretagogue. A partial GH deficiency should be suspected whenever subnormal results are obtained.

#### **Treatment**

The therapy for pituitary dwarfism relies on the administration of GH. Unfortunately, an effective GH product is not available for use in dogs. Canine GH is not available for therapeutic use, GH antibody formation and legal restrictions preclude the use of biosynthetic human GH, and the concentration of biosynthetic bovine GH in commercial products for use in cattle precludes its use in dogs. The amino acid sequence of porcine GH is identical to canine GH, but porcine GH is difficult to find. If available, the recommended subcutaneous dose is 0.1 to 0.3 IU/kg three times per week for 4 to 6 weeks. Because of the synergistic influence of GH and thyroid hormone on growth processes, subnormal concentrations of thyroid hormone may diminish the effectiveness of GH therapy. Dogs and cats with suspected concurrent TSH deficiency should be treated with daily thyroid hormone supplementation, as discussed in Chapter 51.

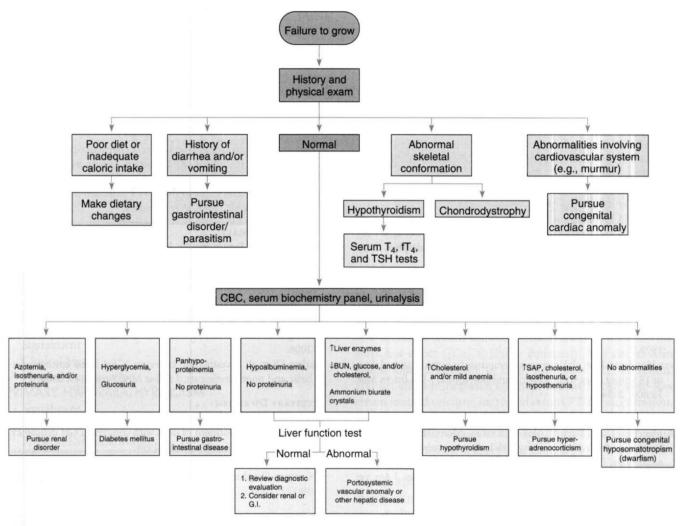

FIG 49-11
Diagnostic approach to the puppy or kitten that fails to grow. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders)

Hypersensitivity reactions (including angioedema), carbohydrate intolerance, and overt diabetes mellitus are the primary adverse reactions associated with GH injections. Frequent monitoring of urine for glycosuria and blood for hyperglycemia should be done, and GH therapy should be stopped if either develops. Regrowth of hair, thickening of the skin, and changes in serum IGF-I and glucose concentrations are used to monitor therapy. A beneficial response in the skin and haircoat usually occurs within 6 to 8 weeks of the start of GH and thyroid hormone supplementation. The hair that grows back is lanugo or secondary hairs; the growth of primary or guard hairs is variable and may occur sporadically over the body. An increase in height is dependent on the status of the growth plates at the time treatment is initiated. A significant increase in height may occur if the growth plates are open, and minimal to no change in height will occur if the growth plates have closed or are about to close at the time treatment is initiated.

An increase in body size and regrowth of a complete haircoat has been reported in pituitary dwarfs treated with medroxyprogesterone acetate at doses of 2.5 to 5.0 mg/kg body weight, initially at 3-week intervals and subsequently at 6-week intervals. Progestogens induce the expression of the GH gene in the mammary gland of dogs, resulting in GH secretion from foci of hyperplastic ductular epithelial cells and increased plasma concentrations of GH and IGF-I. Adverse reactions with progestogen treatment include recurrent pruritic pyoderma, abnormal skeletal development, mammary tumors, diabetes mellitus, acromegaly, and cystic endometrial hyperplasia. Female dogs should be ovariohysterectomized before progestogen treatment. Serum IGF-I and glucose concentrations should be monitored.

#### **Prognosis**

The long-term prognosis for animals with pituitary dwarfism is poor. Most animals die by 5 years of age despite therapy.

Death is usually a result of infections, degenerative diseases, neurologic dysfunction, or renal failure.

# CHAPTER OUTLINE

CLASSIFICATION OF HYPERPARATHYROIDISM PRIMARY HYPERPARATHYROIDISM

Signalment Clinical Signs Physical Examination PRIMARY HYPOPARATHYROIDISM

Signalment Clinical Signs Physical Examination

# CLASSIFICATION OF HYPERPARATHYROIDISM

Hyperparathyroidism is a sustained increase in parathyroid hormone (PTH) secretion. Chief cells located within the parathyroid gland synthesize and secrete PTH—a peptide hormone that controls the minute-to-minute concentration of ionized calcium in the blood and extracellular fluid (ECF). The major regulator of PTH secretion is the concentration of ionized calcium in the blood. Decreased serum ionized calcium increases PTH secretion, and vice versa. PTH stimulates calcium reabsorption and inhibits phosphate reabsorption by the kidney, stimulates synthesis of the active form of vitamin D in the kidney, and stimulates bone resorption. The net effect is to increase serum ionized and total calcium concentration and decrease serum phosphorus concentration.

Hyperparathyroidism can result from a normal physiologic response to decreased serum ionized calcium concentrations (renal, nutritional, and adrenal secondary hyperparathyroidism) or a pathologic condition resulting from excessive synthesis and secretion of PTH by abnormal, autonomously functioning parathyroid chief cells (i.e., primary hyperparathyroidism [PHP]). In PHP increased secretion of PTH is maintained regardless of the serum ionized calcium concentration.

Hypercalcemia and hypophosphatemia develop as a result of the physiologic actions of PTH. In renal secondary hyperparathyroidism renal failure causes retention of phosphate and development of hyperphosphatemia. Hyperphosphatemia decreases serum ionized calcium concentration by the mass law effect ( $[Ca] \times [Pi] = constant$ ). The decrease in serum ionized calcium, in turn, stimulates PTH secretion. The net effect is increased serum phosphate, normal-to-low serum ionized calcium, increased serum PTH concentration, and diffuse parathyroid gland hyperplasia. The etiogenesis of hyperparathyroidism is similar in nutritional secondary hyperparathyroidism, except the decrease in calcium results from feeding diets containing low calcium-to-phosphorus ratios, such as beef heart or liver. Dietary calcium deficiency or phosphorus excess decreases serum calcium concentration, inducing increased PTH secretion and parathyroid gland hyperplasia. An increase in serum PTH has been documented in dogs with hyperadrenocoricism and is believed to be a compensatory response to increased calcium loss and/or increased serum phosphate concentrations—hence the term adrenal secondary hyperparathyroidism. Serum phosphate and PTH decrease and serum calcium increases after successful treatment of hyperadrenocorticism.

# PRIMARY HYPERPARATHYROIDISM

# Etiology

PHP is a disorder resulting from the excessive, relatively uncontrolled secretion of PTH by one or more abnormal parathyroid glands. The physiologic actions of PTH ultimately cause hypercalcemia and hypophosphatemia (Table 50-1). It is an uncommon disorder in the dog and rare in the cat. Parathyroid adenoma is the most common histologic finding; parathyroid carcinoma and parathyroid hyperplasia have also been described in dogs and cats but are uncommon. Parathyroid adenomas are typically small, well-encapsulated, light brown to red tumors located in close apposition to the thyroid gland (Fig. 50-1). The remaining parathyroid glands are normal, atrophied, or not visible at surgery. Parathyroid carcinomas grossly appear similar to adenomas; the

diagnosis of carcinoma is based on finding certain histologic features such as capsular or vascular invasion by the tumor. The biologic behavior of parathyroid carcinoma is not well characterized in dogs and cats. Similarly, the histologic criteria for differentiating between adenoma and hyperplasia is not well established. Although involvement of multiple parathyroid glands suggests hyperplasia, adenoma involving two glands and hyperplasia involving only one gland have been identified in dogs with PHP. In addition, hyperplasia caused by renal and nutritional secondary hyperparathyroidism may not cause uniform enlargement of the parathyroid glands even though the stimulus for enlargement is the same for each gland. Differentiating hyperplasia from adenoma has important prognostic implications. The surgical removal of parathyroid adenoma(s) results in a cure, assuming at least one normal parathyroid gland remains to prevent hypoparathyroidism. In contrast, hypercalcemia caused by parathyroid hyperplasia may persist or recur weeks to months after surgery if the remaining grossly normal-appearing parathyroid tissue is hyperplastic at the time of surgery or becomes hyperplastic in the future.

#### **Clinical Features**

# **SIGNALMENT**

The age at which clinical signs of PHP appear in dogs ranges from 4 to 16 years, with a mean age of 10 years. There is no sex-related predilection. Any breed of dog can be affected, although PHP is most commonly diagnosed in the Keeshond and is an autosomal dominant, genetically transmitted disease in this breed. The age at the time of diagnosis of PHP in cats has ranged from 8 to 20 years, with a mean age of 13 years. The majority of cats have been mixed breed and Siamese. There is no apparent sex predisposition.

#### **CLINICAL SIGNS**

Clinical signs of PHP result from the physiologic actions of excessive PTH secretion rather than from the space-occupying nature of the tumor. Clinical signs are caused by hypercalcemia, which is the hallmark of this disorder, and by the presence of cystic calculi and lower urinary tract infections, which are consequences of the hypercalcemia. Clinical signs are absent in most dogs and cats with the mildest form of

PHP, and hypercalcemia is discovered only after a serum biochemistry panel is performed, often for unrelated reasons. When clinical signs do develop, they initially tend to be nonspecific and insidious in onset. The clinical signs in dogs are typically renal, gastrointestinal, and neuromuscular in origin (Box 50-1). The most common clinical signs in cats with PHP are lethargy, anorexia, and vomiting. Less common clinical signs in cats include constipation, polyuria, polydipsia, and weight loss.

# PHYSICAL EXAMINATION

The physical examination is usually normal, which is an important diagnostic finding when differentiating dogs with PHP from dogs with hypercalcemia of malignancy (see Chapter 55). Lethargy, generalized muscle atrophy, weakness, and cystic calculi (calcium phosphate, calcium oxalate, or both types) may be noted in some dogs with PHP. The severity of weakness is variable but usually subtle. Cervical palpation of a parathyroid mass is rare in dogs with PHP. If a mass is palpated in the neck of a dog with hypercalcemia, thyroid gland carcinoma; squamous cell carcinoma; lymphoma; and, least likely, parathyroid gland carcinoma should be considered. In contrast, cats with PHP often have a palpable parathyroid mass that is typically located in the region of the thyroid gland. As such, a palpable mass in the ventral cervical region of the neck should raise suspicion for hyperthyroidism (common) as well as PHP (rare) in cats.

# Diagnosis

PHP should be suspected in a dog or cat with persistent hypercalcemia and normophosphatemia to hypophosphatemia. The serum calcium concentration is typically 12 to 15 mg/dl but can exceed 16 mg/dl. The serum ionized calcium concentration is typically 1.4 to 1.8 mmol/L but can exceed 2.0 mmol/L. The serum phosphorus concentration is typically less than 4 mg/dl, unless concurrent renal insufficiency is present. Although hypercalcemia in dogs and

cats has several causes (Table 50-2), the primary differential diagnoses for hypercalcemia and hypophosphatemia are humoral hypercalcemia of malignancy (most notably lymphoma in dogs and carcinomas in cats) and PHP (see Chapter 55). The history, findings on physical examination, results of routine blood and urine tests, thoracic radiographs, abdominal and cervical ultrasound, and measurement of PTH and parathyroid hormone-related peptide (PTHrp) will usually establish the diagnosis. With PHP clinical signs are usually mild to absent, the physical examination is normal, and results of routine blood work, thoracic and abdominal radiography, and abdominal ultrasonography are unremarkable, except for hypercalcemia, hypophosphatemia, and cystic calculi. Additional tests used to identify lymphoma as the cause of hypercalcemia (i.e., cytologic evaluations of bone marrow and lymph node, liver, and splenic aspirates and PTHrp concentrations) are normal in dogs with PHP.

Renal failure in a dog with hypercalcemia can create a diagnostic dilemma. Fortunately, development of hypercalcemia-induced renal failure rarely occurs in dogs with PHP. Prolonged severe hypercalcemia may cause progressive nephrocalcinosis, renal damage, and azotemia, but most dogs with PHP have mild hypercalcemia and concurrent hypophosphatemia; the latter protects the kidney by keeping the calcium × phosphorus product less than 50. Measurement of serum ionized calcium concentration will help identify the etiology of hypercalcemia in dogs with concurrent renal failure. Serum ionized calcium concentration is typically normal in dogs with renal failure-induced hypercalcemia and increased in dogs with PHP and concurrent renal failure. Urine specific gravity is usually not helpful when assessing renal function in dogs with hypercalcemia because of the interference of calcium with the actions of vasopressin on renal tubular cells. Urine specific gravities less than 1.015 are common in dogs with PHP. Hematuria, pyuria, bacteriuria, and crystalluria may be identified if cystic calculi and secondary bacterial cystitis develop. Hypercalciuria, proximal renal tubular acidosis with impaired bicarbonate resorption, and the production of alkaline urine may predispose dogs to the development of cystic or renal calculi and bacterial cystitis. In one study urinary tract infection was identified in 29% and cystic calculi in 31% of 210 dogs with PHP (Feldman et al., 2005). Uroliths are typically composed of calcium phosphate, calcium oxalate, or mixtures of the two salts.

Cervical ultrasound should identify one or more enlarged parathyroid glands in dogs and cats with PHP (Fig. 50-2). The parathyroid glands of healthy dogs are typically 3 mm or less in maximum width when visualized ultrasonographically. The maximum width of the abnormal parathyroid glands ranged from 3 to 23 mm (median 6 mm) in 130 dogs with PHP (Feldman et al., 2005). A solitary parathyroid mass was identified in 89%, and two parathyroid masses were identified in 10% of the dogs.

Measurement of baseline serum PTH concentration is used to establish the diagnosis of PHP. The two-site immunoradiometric (IRMA) assay system is currently used by

# Causes of Hypercalcemia in Dogs and Cats

#### DISORDER

Primary hyperparathyroidism Hypercalcemia of malignancy

Humorally mediated: LSA, apocrine gland adenocarcinoma, carcinoma (nasal, mammary gland, gastric, thyroid, pancreatic, pulmonary)

Locally osteolytic (multiple myeloma, LSA, squamous cell carcinoma, osteosarcoma, fibrosarcoma)

Hypervitaminosis D

Cholecalciferol rodenticides, plants

Excessive supplementation

Hypoadrenocorticism

Renal failure

Idiopathic—cats

Granulomatous disease (uncommon)

Systemic mycosis—Blastomycosis

Schistosomiasis, FIP

Nonmalignant skeletal disorder (rare)

Osteomylelitis

Hypertrophic osteodystrophy

latrogenic disorder

Excessive calcium supplementation

Excessive oral phosphate binders

Dehydration (mild hyercalcemia)

Factitious disorder

Lipemia

Postprandial measurement

Young animal (<6 months)

Laboratory error

#### TESTS TO HELP ESTABLISH THE DIAGNOSIS

Serum PTH concentration, cervical ultrasound, surgery Physical examination, thoracic and abdominal radiography, abdominal ultrasonography, aspiration of lymph nodes, liver, spleen and bone marrow, serum PTHrp

History, serum biochemistry panel, serum vitamin D concentration

Serum electrolytes, ACTH stimulation test Serum biochemistry panel, urinalysis Rule out by exclusion

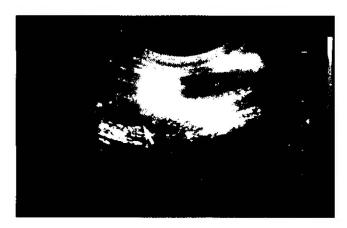

Thoracic radiography, abdominal ultrasonography, fundic examination, cytologic studies of pulmonary wash samples or intestinal biopsy specimens, serum fungal titers

Radiography of peripheral skeleton

History

Repeat calcium measurement

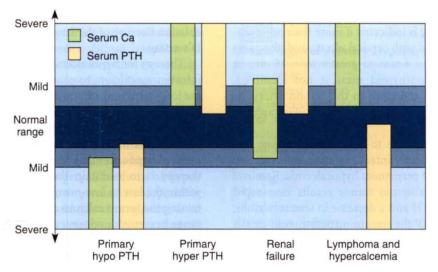

PTH, Parathyroid hormone; LSA, lymphosarcoma; PTHrp, parathyroid hormone-related peptide; ACTH, adrenocorticotropic hormone; FIP, feline infectious peritonitis.

#### FIG 50-2

Ultrasound image of the right thyroid lobe of a 13-year-old Labrador Retriever with hypercalcemia and primary hyperparathyroidism. A hypoechoic mass is seen in the region of the parathyroid gland (arrow). Hypercalcemia resolved following heat ablation of the parathyroid mass.

most veterinary laboratories and is considered the most reliable assay system for PTH quantification in dogs and cats. Most laboratories have a similar PTH reference range for dogs (2 to 13 pmol/L) and cats (0.8 to 4.6 pmol/L). The major regulator of PTH secretion is the concentration of ionized calcium in the blood. Decreased serum ionized calcium increases PTH secretion, and vice versa. Serum PTH test results should always be interpreted in conjunction with serum calcium or, preferably, serum ionized calcium measured from the same blood sample. If the parathyroid gland is functioning normally, the serum PTH concentration should be below the reference range or undetectable in the face of hypercalcemia because of the inhibitory effects of an increased serum calcium concentration on parathyroid gland function. Dogs with nonparathyroid-induced hypercalcemia should also have low to undetectable serum PTH concentrations. Serum PTH concentration within or above the reference range is inappropriate in the face of hypercalcemia and indicative of an autonomously functioning

**FIG 50-3**Ranges of the serum calcium and parathyroid hormone concentrations in the more common disorders causing alterations in serum calcium concentration, parathyroid gland function, or both. *PTH*, Parathyroid hormone; *hypo PTH*, hypoparathyroidism; *hyper PTH*, hyperparathyroidism.

A mass is in the region of the parathyroid gland (arrow), and a needle has been inserted into the mass using ultrasound guidance before heat ablation of the mass. **B,** Heat is being administered to the mass, causing hyperechogenicity of the mass (arrow).

parathyroid gland (Fig. 50-3). In 185 dogs with PHP none had serum PTH concentration below the reference range, 45% were in the lower half of the reference range (2.3 to 7.9 pmol/L), 28% were in the upper half of the reference range (8.0 to 13.0 pmol/L), and 27% had increased serum PTH concentrations (13 to 121 pmol/L; Feldman et al., 2005).

#### **Treatment**

Surgical removal of the abnormal parathyroid tissue is the treatment of choice. Slatter (2003) and Fossum (2007) have adequately described the surgical techniques for the thyroparathyroid complex (see Suggested Readings). Almost all dogs and cats with PHP have a solitary, easily identified parathyroid adenoma (see Fig. 50-1). Enlargement of more than one parathyroid gland indicates the presence of either multiple adenomas or parathyroid hyperplasia. If none of

the parathyroid glands appear enlarged or if all appear small, the diagnosis of PHP must be questioned and hypercalcemia stemming from occult neoplasia or PTH production by a parathyroid tumor in an ectopic site (e.g., cranial mediastinum) or by a nonparathyroid tumor should be considered.

Chemical (i.e., ethanol) and heat ablation of abnormal parathyroid tissue performed under ultrasound guidance are also effective treatments for PHP (Fig. 50-4). Surgery is avoided, anesthetic time is significantly reduced, and there are no incisions or issues related to wound healing. However, the management of the dog after chemical or heat ablation is identical to the management after surgical removal of the parathyroid mass. In a recent retrospective study surgical removal, heat ablation, and chemical ablation of the parathyroid mass were successful in controlling hypercalcemia in 94%, 90%, and 72% of dogs treated for PHP, respectively

(Rasor et al., 2007). Not all dogs are candidates for chemical or heat ablation. Surgery is indicated if more than one parathyroid mass is identified with cervical ultrasound, the parathyroid mass is less than 4 mm or greater than 15 mm in maximum width, a parathyroid mass is not identified, the parathyroid mass is too close to the carotid artery, or cystic calculi are identified with abdominal radiographs or ultrasound.

An attempt must be made to ensure that at least one parathyroid gland remains intact to maintain calcium homeostasis and prevent permanent hypocalcemia. Removal or ablation of the parathyroid tumor results in a rapid decline in circulating PTH and a decrease in serum calcium. In the early stages of PHP the remaining parathyroid glands may secrete PTH in response to the decrease in serum calcium, thereby preventing development of severe hypocalcemia. In dogs with more advanced PHP, atrophy of the normal parathyroid glands may prevent a response to the decrease in serum calcium, leading to severe hypocalcemia and clinical signs within 7 days of surgery or ablation. In these dogs intravenous and oral calcium and oral vitamin D therapy must be initiated to correct and/or prevent hypocalcemia.

There are two approaches for managing the dog (and cat) once the parathyroid tumor has been removed with surgery or ablation. One approach is to arbitrarily treat all dogs with oral calcium and vitamin D at the time the parathyroid tumor is removed, and another approach is to withhold calcium and vitamin D therapy until the serum calcium concentration decreases below a safe concentration, typically a serum calcium or ionized calcium concentration of 9.0 mg/ dl and 0.9 mmol/L, respectively, and before clinical signs of hypocalcemia develop. Regardless of which approach is taken, serum total or ionized calcium should be monitored once or twice a day until the serum calcium concentration is stable and in the reference range. I prefer to withhold calcium and vitamin D therapy in dogs in which I suspect parathyroid gland atrophy is mild and calcium and vitamin D therapy may not be needed. The higher the preoperative serum calcium concentration or the more chronic the hypercalcemic condition, or both, the more likely the dog will become clinically hypocalcemic after removal of the abnormal parathyroid gland or glands. As a general rule, I do not initially treat hyperparathyroid dogs with oral calcium and vitamin D if the serum calcium or ionized calcium concentration before surgery or ablation is less than 14 mg/dl or 1.6 mmol/L, respectively, and hypercalcemia has been present for less than 6 months. Serum calcium or ionized calcium concentrations greater than 14 mg/dl and 1.6 mmol/L, respectively, and hypercalcemia that has been present for greater than 6 months suggest the existence of significant atrophy of the remaining parathyroid glands and a high probability for the development of signs of hypocalcemia after surgery or ablation. In these dogs oral calcium and vitamin D therapy is started at the time PHP is treated. In dogs with severe hypercalcemia (total calcium or ionized calcium > 18 mg/dl and 2.0 mmol/L, respectively), vitamin D

therapy can be initiated 24 to 36 hours before surgery or ablation because of the known delay in the onset of vitamin D's action.

Therapy for hypocalcemia includes the administration of intravenous calcium to control immediate clinical signs and the long-term oral administration of calcium and vitamin D supplements to maintain low-normal blood calcium concentrations while the parathyroid gland atrophy resolves. (See Chapter 55 and Box 55-7 for details about the management of hypocalcemia.) The goal of calcium and vitamin D therapy is to maintain the serum calcium concentration within the low to low-normal range (9 to 10 mg/dl). Maintaining the serum calcium concentration in the low-normal range prevents development of clinical signs of hypocalcemia, minimizes the risk of hypercalcemia, and stimulates a return of function in the remaining atrophied parathyroid glands. Once the parathyroid glands regain control of calcium homeostasis and the serum calcium concentration is stable in the dog or cat in the home environment, the calcium and vitamin D supplements can be gradually withdrawn over a period of 3 to 6 months. This gradual withdrawal allows time for the parathyroid glands to become fully functional and thereby prevents hypocalcemia. Vitamin D therapy is withdrawn by gradually increasing the number of days between administrations. The dosing interval should be increased by 1 day every 2 to 3 weeks, after the serum calcium concentration has been measured and found to be 9 mg/dl or greater. Vitamin D therapy can be discontinued once the dog or cat is clinically normal, the serum calcium concentration is stable between 9 and 11 mg/dl, and the vitamin D dosing interval is every 7 days.

## **Prognosis**

The prognosis for dogs and cats undergoing surgical or ablation therapy for PHP is excellent, assuming severe hypocalcemia is avoided postoperatively and PHP is caused by a parathyroid adenoma. Hypercalcemia may recur weeks to months after surgery in dogs and cats with PHP caused by parathyroid hyperplasia if one or more parathyroid glands have been left in situ.

# PRIMARY HYPOPARATHYROIDISM

#### **Etiology**

Primary hypoparathyroidism develops as a result of an absolute or relative deficiency in the secretion of PTH. This deficiency ultimately causes hypocalcemia and hyperphosphatemia because of a loss of the effects of PTH on bone, kidney, and intestine (see Table 50-1). The major signs of hypoparathyroidism are directly attributable to the decreased concentration of ionized calcium in the blood, which leads to increased neuromuscular activity.

Spontaneous primary hypoparathyroidism is uncommon in dogs and cats. Most cases are classified as idiopathic (i.e., there is no evidence of trauma, malignant or surgical destruction, or other obvious damage to the neck or parathyroid glands). The glands are difficult to locate visually and show microscopic evidence of atrophy. Histologic evaluation of the parathyroid gland may reveal a diffuse lymphocytic, plasmacytic infiltration and fibrous connective tissue, suggesting an underlying immune-mediated cause of the disorder.

latrogenic hypoparathyroidism after performance of bilateral thyroidectomy for the treatment of hyperthyroidism is common in cats. The parathyroid tissue in such animals may be excised or traumatized, or its blood supply may be compromised during surgery. This form of hypoparathyroidism may be transient or permanent, depending on the viability of the parathyroid gland or glands saved at the time of surgery. Only one viable parathyroid gland is needed to maintain a normal serum calcium concentration.

Transient hypoparathyroidism may develop secondary to severe magnesium depletion (serum magnesium concentration <1.2 mg/dl). Severe magnesium depletion may suppress PTH secretion without parathyroid destruction, increase end-organ resistance to PTH, and impair the synthesis of the active form of vitamin D (i.e., calcitriol). The end result is mild hypocalcemia and hyperphosphatemia. Magnesium repletion reverses the hypoparathyroidism. Serum magnesium concentrations in dogs and cats with spontaneous primary hypoparathyroidism usually have been normal when measured. (See Chapter 55 for more information on magnesium.)

# **Clinical Features**

#### **SIGNALMENT**

The age at which the clinical signs of hypoparathyroidism appear in dogs ranges from 6 weeks to 13 years, with a mean of 4.8 years. There may be a sex-related predisposition in female dogs. There is no apparent breed-related predisposition, although Toy Poodles, Miniature Schnauzers, Labrador Retrievers, German Shepherd Dogs, and Terriers are commonly affected breeds. However, this increased prevalence may merely reflect the popularity of these breeds. Only a few cases of naturally acquired primary hypoparathyroidism in cats have been reported. To date, these cats have been young to middle-aged (6 months to 7 years), of several breeds, and usually male.

# **CLINICAL SIGNS**

The clinical signs and physical examination findings in dogs and cats with primary hypoparathyroidism are similar. The major clinical signs are directly attributable to hypocalcemia, most notably its effects on the neuromuscular system. Neuromuscular signs include nervousness, generalized seizures, focal muscle twitching, rear-limb cramping or tetany, ataxia, and weakness (Box 50-2). Additional signs include lethargy, inappetence, intense facial rubbing, and panting. The onset of clinical signs tends to be abrupt and severe and to occur more frequently during exercise, excitement, and stress. Clinical signs also tend to occur episodically. Episodes of

BOX 50-2

Clinical Signs of Primary Hypoparathyroidism in Dogs

Nervousness
Generalized seizures
Rear leg cramping or pain
Focal muscle fasciculations, twitching
Ataxia, stiff gait
Facial rubbing (intense)
Aggressive behavior
Panting
Weakness
Inappetence
Listlessness, lethargy

Biting, licking paws (intense)

clinical hypocalcemia are interspersed with relatively normal periods, lasting minutes to days. Interestingly, hypocalcemia persists during these clinically "normal" periods,

#### PHYSICAL EXAMINATION

The most common physical examination findings are related to muscular tetany and include a stiff gait; muscle rigidity; a tense, splinted abdomen; and muscle fasciculations. Fever, panting, and nervousness, often so pronounced that they interfere with the examination, are also common. Potential cardiac abnormalities include bradycardia, paroxysmal tachyarrhythmias, muffled heart sounds, and weak femoral pulses. Cataracts have been noted in a few dogs and cats with primary hypoparathyroidism. Cataracts were small, punctate-to-linear, white opacities that were randomly distributed in the anterior and posterior cortical subcapsular region of the lens; there was no loss of vision. The physical examination is occasionally normal, despite the previous history of neuromuscular disorders.

#### Diagnosis

Primary hypoparathyroidism should be suspected in a dog or cat with persistent hypocalcemia, hyperphosphatemia, and normal renal function. The serum calcium concentration is usually less than 7 mg/dl, the serum ionized calcium is usually less than 0.8 mmol/L, and the serum phosphorus is usually greater than 6 mg/dl. Low serum calcium and high serum phosphorus concentrations can also be encountered during nutritional and renal secondary hyperparathyroidism, after phosphate-containing enema, and during tumor lysis syndrome. The diagnosis of primary hypoparathyroidism is established by identifying an undetectable serum PTH concentration in the face of severe hypocalcemia in a dog or cat in which other causes of hypocalcemia have been ruled out (Table 50-3). Most causes of hypocalcemia can be identified after evaluation of the history, findings on physical examination, and results of routine blood and urine tests and an abdominal ultrasound. The history and physical examination findings are essentially unremarkable in dogs

# Causes of Hypocalcemia in Dogs and Cats

DISORDER	TESTS TO HELP ESTABLISH THE DIAGNOSIS

PTH, parathyroid hormone; PLI, pancreatic lipase immunoreactivity; Mg, magnesium.

and cats with primary hypoparathyroidism, other than those findings caused by hypocalcemia. The only relevant abnormalities identified on routine blood and urine tests are severe hypocalcemia and, in most dogs and cats, hyperphosphatemia. The serum total protein, albumin, urea nitrogen, creatinine, and magnesium concentrations are normal. Abdominal ultrasound is also normal.

Measurement of serum PTH concentration helps confirm a diagnosis of primary hypoparathyroidism. Blood for PTH determination should be obtained before the initiation of calcium and vitamin D therapy while the animal is still hypocalcemic. The two-site IRMA assay system is currently used by most veterinary laboratories and is considered the most reliable assay system for PTH quantification in dogs and cats. Interpretation of the serum PTH concentration must be done in conjunction with the serum calcium concentration. If the parathyroid gland is functioning normally, the serum PTH concentration should be increased in the face of hypocalcemia because of the stimulatory effects of a decreased serum ionized calcium concentration on parathyroid gland function. A low-to-undetectable serum PTH concentration in a hypocalcemic dog or cat is strongly suggestive of primary hypoparathyroidism (see Fig. 50-3). Dogs and cats with nonparathyroid-induced hypocalcemia should have normal or high serum PTH concentrations; the exceptions are those disorders causing severe hypomagnesemia.

# **Treatment**

The therapy for primary hypoparathyroidism involves the administration of vitamin D and calcium supplements (see Chapter 55 and Box 55-7). Therapy is typically divided into

two phases. The first phase (i.e., acute therapy) should initially control hypocalcemic tetany and involves the slow administration of calcium gluconate (not calcium chloride) intravenously, to effect. Once clinical signs of hypocalcemia are controlled, calcium gluconate should then be administered by continuous intravenous infusion until orally administered calcium and vitamin D therapy (i.e., second phase of therapy) becomes effective. Calcium gluconate is initially administered at a dose of 60 to 90 mg/kg per day (approximately 2.5 ml/kg of 10% calcium gluconate added to the infusion solution and administered every 6 to 8 hours). Calcium should not be added to solutions containing lactate, bicarbonate, acetate, or phosphates because of the potential for precipitation problems. Serum calcium concentrations should be monitored twice a day and the rate of infusion adjusted as needed to control clinical signs and maintain the serum calcium concentration greater than 8 mg/dl.

The second phase of therapy (i.e., maintenance therapy) should maintain the blood calcium concentration between 8 and 10 mg/dl through the daily administration of vitamin D and calcium. These calcium concentrations are above the level at which there is a risk for clinical hypocalcemia and below the level at which hypercalciuria (risk of calculi formation) or severe hypercalcemia and hyperphosphatemia (risk of nephrocalcinosis and renal failure) may occur. Maintenance therapy should be initiated once the hypocalcemic tetany is controlled with intravenous calcium therapy. The onset of action of vitamin D varies depending on the formulation of vitamin D that is administered. In general, 1,25-dihydroxy-vitamin D<sub>3</sub> (calcitriol) has the fastest onset of

action and is preferred for treating hypoparathyroidism. The initial dosage of calcitriol is 0.02 to 0.03 µg/kg/day. Dogs and cats should ideally remain hospitalized until their serum calcium concentration remains between 8 and 10 mg/dl without parenteral support. Serum calcium concentrations should be monitored weekly, with the vitamin D dose adjusted to maintain a concentration of 8 to 10 mg/dl. The aim of therapy is to prevent hypocalcemic tetany and not induce hypercalcemia. Serum calcium concentrations of more than 10 mg/dl are unnecessary to prevent tetany and only increase the likelihood of unwanted hypercalcemia.

Once the serum calcium concentration has stabilized, attempts can be made to slowly taper the dose of oral calcium and then vitamin D to the lowest dose that maintains the serum calcium concentration between 8 and 10 mg/dl. Vitamin D is critical for establishing and maintaining a normal blood calcium concentration. Most dogs and cats with primary hypoparathyroidism require permanent vitamin D therapy. The calcium supplement can often be gradually tapered over a period of 2 to 4 months and then stopped once the animal's serum calcium concentration is stable between 8 and 10 mg/dl. Calcium in the diet is often sufficient for maintaining the calcium needs of the animal. Supplementing the diet with calcium-rich foods (e.g., dairy products) helps ensure an adequate source of dietary calcium. Once the animal's serum calcium concentration is stable and maintenance therapy has become established, reevaluation of the serum calcium concentration every 3 to 4 months is advisable.

# **Prognosis**

The prognosis depends on the dedication of the client. The prognosis is excellent if proper therapy is instituted and timely reevaluations are performed. Proper management requires close monitoring of the serum calcium concentration. The more frequent the rechecks, the better the chance

of preventing extremes in the concentration and the better the chance of a normal life expectancy.

#### HYPOTHYROIDISM IN DOGS

# **Etiology**

Structural or functional abnormalities of the thyroid gland can lead to deficient production of thyroid hormones. A convenient classification scheme for hypothyroidism has been devised that is based on the location of the problem within the hypothalamic-pituitary-thyroid gland complex (Fig. 51-1). Primary hypothyroidism is the most common form of this disorder in dogs; it results from problems within the thyroid gland, usually destruction of the thyroid gland (Box 51-1). The two most common histologic findings in this disorder are lymphocytic thyroiditis and idiopathic atrophy of the thyroid gland (Fig. 51-2). Lymphocytic thyroiditis is an immune-mediated disorder characterized by a diffuse infiltration of lymphocytes, plasma cells, and macrophages into the thyroid gland. The factors that trigger the development of lymphocytic thyroiditis are poorly understood. Genetics undoubtedly plays a major role, especially given the increased incidence of this disorder in certain breeds and in certain lines within a breed (Table 51-1). Environmental risk factors have not been well defined in the dog. A link between infection-induced damage to the thyroid gland and development of lymphocytic thyroiditis has been the subject of speculation but has not been proved. Vaccine administration has also been hypothesized to be a contributing factor for development of lymphocytic thyroiditis but also has not been proved.

Destruction of the thyroid gland is progressive, and clinical signs may not become evident until more than 75% of the gland is destroyed. Development of decreased serum thyroid hormone concentrations and clinical signs is usually a gradual process, often requiring 1 to 3 years to develop, which suggests that the destructive process is slow.

Idiopathic atrophy of the thyroid gland is characterized by loss of the thyroid parenchyma. There is no inflammatory infiltrate, even in areas where small follicles or follicular remnants are present in the thyroid gland. Tests for lymphocytic thyroiditis are negative. The cause of idiopathic thyroid atrophy is not known. It may be a primary degenerative

disorder or represent an end stage of autoimmune lymphocytic thyroiditis.

Secondary hypothyroidism results from failure of pituitary thyrotrophs to develop (pituitary hypoplasia causing pituitary dwarfism; see Chapter 49) or from dysfunction within the pituitary thyrotropic cells causing impaired secretion of thyroid-stimulating hormone (TSH) and a "secondary" deficiency in thyroid hormone synthesis and secretion. Follicular atrophy in the thyroid gland gradually develops owing to lack of TSH. Secondary hypothyroidism could also result from destruction of pituitary thyrotrophs (e.g., pituitary neoplasia [rare]) or suppression of thyrotroph function by hormones or drugs (e.g., glucocorticoids [common]; see Box 51-1).

Tertiary hypothyroidism is a deficiency in the secretion of thyrotropin-releasing hormone (TRH) by peptidergic neurons in the supraoptic and paraventricular nuclei of the hypothalamus. Lack of TRH secretion should cause a deficiency in TSH secretion and secondary follicular atrophy in the thyroid gland. Tertiary hypothyroidism has not been reported in dogs.

Congenital primary hypothyroidism is uncommon in dogs and has been caused by deficient dietary iodine intake, dyshormonogenesis (i.e., an iodine organification defect), and thyroid dysgenesis. Secondary hypothyroidism resulting from an apparent deficiency of TSH has also been reported in a family of Giant Schnauzers and in a Boxer. Pedigree analysis showed that it may be inherited in an autosomal

recessive fashion in the family of Giant Schnauzers. Development of an enlarged thyroid gland (i.e., goiter) depends on the etiology. If the hypothalamic-pituitary-thyroid gland axis is intact (e.g., as occurs with an iodine organification defect), goiter will develop, and if it is not intact (e.g., as occurs with pituitary TSH deficiency), goiter will not develop.

# **Clinical Features**

Clinical signs of the more common forms of primary hypothyroidism usually develop during middle age (i.e., 2 to 6 years). Clinical signs tend to develop at an earlier age in breeds at increased risk than in other breeds (see Table 51-1). There is no apparent sex-related predilection.

Clinical signs are quite variable and depend in part on the age of the dog at the time a deficiency in thyroid hormone develops (Box 51-2). Clinical signs may also differ between breeds. For example, truncal alopecia may dominate in some breeds, whereas thinning of the haircoat dominates in other breeds. In adult dogs the most consistent clinical signs of hypothyroidism result from decreased cellular metabolism

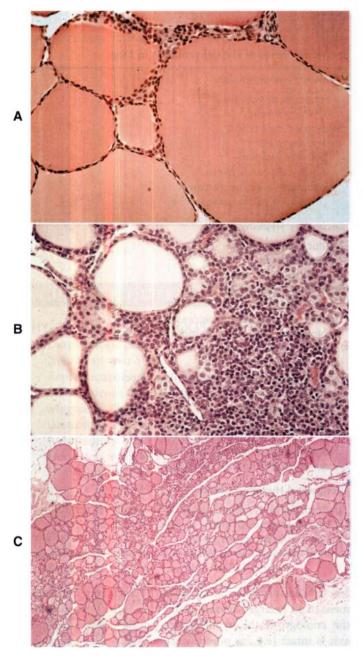

FIG 51-2

and its effects on the dog's mental status and activity. Most dogs with hypothyroidism show some mental dullness, lethargy, exercise intolerance or unwillingness to exercise, and a propensity to gain weight without a corresponding increase in appetite or food intake. These signs are often gradual in onset, subtle, and not recognized by the client until after thyroid hormone supplementation has been initiated. Additional clinical signs of hypothyroidism typically involve the skin and, less commonly, the neuromuscular system.

#### **DERMATOLOGIC SIGNS**

Alterations in the skin and haircoat are the most common observable abnormalities in dogs with hypothyroidism. The classic cutaneous signs include bilaterally symmetric, non-pruritic truncal alopecia that tends to spare the head and extremities (Fig. 51-3). Alopecia may be local or generalized and symmetric or asymmetric, it may involve only the tail (i.e., "rat tail"), and it often initially starts over sites of wear

and friction. Although nonpruritic endocrine alopecia is not pathognomonic for hypothyroidism (see Chapter 49), hypothyroidism is certainly the most likely diagnosis in an affected dog with lethargy, weight gain, and no polyuria-polydipsia.

Seborrhea and pyoderma are also common signs of hypothyroidism. Depletion of thyroid hormone suppresses humoral immune reactions, impairs T-cell function, and reduces the number of circulating lymphocytes—defects that can be reversed by exogenous thyroid hormone therapy. All forms of seborrhea (i.e., sicca, oleosa, dermatitis) are possible. Seborrhea and pyoderma may be focal, multifocal, or generalized. Because both frequently result in pruritus, hypothyroid dogs with secondary pyoderma or seborrhea may initially be brought to the veterinarian because of a pruritic skin disorder.

The haircoat in dogs with hypothyroidism is often dull, dry, and easily epilated. Hair regrowth is slow. Hyperkeratosis leads to the development of scales and dandruff. Variable degrees of hyperpigmentation may also be noted. Chronic otitis externa has been noted in some dogs with hypothyroidism. In severe cases of hypothyroidism acidic and neutral mucopolysaccharides may accumulate in the

dermis, bind water, and cause skin to thicken. Referred to as *myxedema*, the condition causes the skin to thicken predominantly in the forehead and face of dogs, resulting in rounding of the temporal region of the forehead, puffiness and thickening of the facial skin folds, and drooping of the upper eyelids.

# **NEUROMUSCULAR SIGNS**

Neurologic signs may be the predominant problem in some dogs with hypothyroidism (see Box 51-2). Hypothyroidism-induced segmental demyelination and axonopathy may cause signs referable to the central or peripheral nervous system. Clinical signs referable to the central nervous system (CNS) may also appear after mucopolysaccharide accumulates in the perineurium and endoneurium or after cerebral atherosclerosis, transient ischemia or brain infarctions, or the development of severe hyperlipidemia and include seizures, ataxia, circling, weakness, and proprioceptive and postural reaction deficits. These signs are often present in conjunction with vestibular signs (e.g., head tilt, nystagmus) or facial nerve paralysis. Peripheral neuropathies include facial nerve paralysis, weakness, and

<sup>\*</sup> Common.

In both dogs note the truncal distribution of the dermatologic problem with sparing of the head and distal extremities. **D,** An 8-year-old male castrated Beagle with hypothyroidism, obesity, and myxedema of the face. Note the "tragic facial expression" and "mental dullness" evident from the dog's facial expression. **E,** A 7-month-old female Malamute with congenital hypothyroidism. Note the retention of the puppy haircoat and small stature of the dog.

knuckling or dragging of the feet, with excessive wear of the dorsal part of the toenail. Muscle wasting may also be evident, although myalgia is not common. Thyroxine-responsive unilateral forelimb lameness has also been observed in dogs. The relationship between hypothyroidism and laryngeal paralysis or esophageal hypomotility remains controversial, in part because it is difficult to prove a cause-and-effect relationship between these disorders and because treatment of hypothyroidism often does not improve the clinical signs caused by laryngeal paralysis or esophageal hypomotility.

#### REPRODUCTIVE SIGNS

Historically, hypothyroidism was believed to cause lack of libido, testicular atrophy, and oligospermia to azoospermia in male dogs. However, work by Johnson et al. (1999) in Beagles failed to document any deleterious effect of experimentally induced hypothyroidism on any aspect of male reproductive function. Although other classic clinical signs and clinicopathologic abnormalities of hypothyroidism developed in dogs studied, libido, testicular size, and total sperm count per ejaculate remained normal. These findings indicate that hypothyroidism may, at best, be an uncommon cause of reproductive dysfunction in male dogs, assuming that the Beagle is representative of other dog breeds.

Clinical experience has shown that hypothyroidism can cause prolonged interestrus intervals and failure to cycle in the bitch. Additional reproductive abnormalities include weak or silent estrous cycles, prolonged estrual bleeding (which may be caused by acquired problems in the coagulation system), and inappropriate galactorrhea and gynecomastia. An association between hypothyroidism and fetal resorption, abortion, and stillbirth has been suggested in the bitch; however, published documentation of this association is lacking. Maternal hypothyroidism has also been suggested to result in the birth of weak puppies that die shortly after birth.

# MISCELLANEOUS CLINICAL SIGNS

Ocular, cardiovascular, gastrointestinal, and clotting abnormalities are uncommon clinical manifestations of hypothyroidism (see Box 51-2). More commonly, biochemical or functional abnormalities of these organ systems are identified in dogs exhibiting the more common clinical signs of hypothyroidism. Echocardiography may identify a decrease in cardiac contractility that is usually mild and asymptomatic but that may become relevant during a surgical procedure requiring prolonged anesthesia and aggressive fluid therapy.

A reduction in the activity of factor VIII—related antigen (von Willebrand factor) activity has been inconsistently documented in dogs with hypothyroidism, and the development of clinical signs of a bleeding disorder in hypothyroid dogs is uncommon. An evaluation of the coagulation cascade or von Willebrand factor activity is not indicated in dogs with untreated hypothyroidism unless there are concurrent bleeding problems. Thyroid hormone supplementation has

a variable and sometimes deleterious effect on the blood concentration of von Willebrand factor in euthyroid dogs with von Willebrand's disease.

A cause-and-effect relationship between hypothyroidism and behavioral problems (e.g., aggression) has not been well established in dogs. To date, most reports have been anecdotal and based on improvement in behavior following initiation of thyroid hormone treatment. An inverse relationship between development of aggression and serotonin activity in the CNS has been documented in several species, including dogs. Serotonin turnover and sympathetic activity in the CNS increase in rats made hypothyroid after surgical thyroidectomy, dopamine receptor sensitivity is affected by thyroid hormone in rats, and thyroid hormone potentiates the activity of tricyclic antidepressants in humans suffering from certain types of depression. These studies suggest that thyroid hormone may have an influence on the serotonindopamine pathway in the CNS, regardless of the functional status of the thyroid gland. The benefits, if any, of using thyroid hormone to treat behavioral disorders such as aggression in dogs remain to be clarified.

## MYXEDEMA COMA

Myxedema coma is an uncommon syndrome of severe hypothyroidism characterized by profound weakness, hypothermia, bradycardia, and a diminished level of consciousness that can rapidly progress to stupor and then coma. Physical findings include profound weakness; hypothermia; nonpitting edema of the skin, face, and jowls (i.e., myxedema); bradycardia; hypotension; and hypoventilation. Laboratory findings may include hypoxemia, hypercarbia, hyponatremia, and hypoglycemia in addition to the typical findings of hyperlipidemia, hypercholesterolemia, and nonregenerative anemia. Serum thyroid hormone concentrations are usually extremely low or undetectable; serum TSH concentration is variable but typically increased. Treatment consists of intravenous levothyroxine (5 µg/kg q12h) and supportive care aimed at correcting hypothermia, hypovolemia, electrolyte disturbances, and hypoventilation. Once the dog has stabilized, oral levothyroxine can be started (see p. 741).

# **CRETINISM**

Hypothyroidism in puppies is termed *cretinism*. As the age of onset increases, the clinical appearance of animals with cretinism merges imperceptibly with that of adult hypothyroidism. Retarded growth and impaired mental development are the hallmarks of cretinism (Box 51-3). Dogs with cretinism have a disproportionate body size, with large, broad heads; thick, protruding tongues; wide, square trunks; and short limbs (Fig. 51-4). This is in contrast to the proportionate dwarfism caused by growth hormone deficiency. Cretins are mentally dull and lethargic and do not show the typical playfulness seen in normal puppies. Persistence of the puppy haircoat, alopecia, inappetence, delayed dental eruption, and goiter are additional signs. Differential diagnoses for failure to grow include endocrine (e.g., dwarfism) and nonendo-

crine causes (see Box 49-4 and Fig. 49-11). The presence of goiter is variable and dependent on the underlying etiology.

# AUTOIMMUNE POLYENDOCRINE SYNDROMES

Because autoimmune mechanisms play an important role in the pathogenesis of lymphocytic thyroiditis, it is not surpris-

BOX 51-3

ing that lymphocytic thyroiditis may occur in conjunction with other immune-mediated endocrinopathies. Presumably, the immune-mediated attack is directed against antigens shared by the endocrine system. In human beings autoimmune polyglandular syndrome type II (Schmidt's syndrome) is the most common of the immunoendocrinopathy syndromes, and it usually consists of primary adrenal insufficiency, autoimmune thyroid disease, and type 1 diabetes mellitus. Autoimmune polyendocrine syndromes are uncommon in dogs and should be suspected in a dog found to have multiple endocrine gland failure. Hypothyroidism; hypoadrenocorticism; and, to a lesser extent, diabetes mellitus, hypoparathyroidism, and lymphocytic orchitis are recognized combined syndromes. In most affected dogs each endocrinopathy is manifested separately, with additional disorders ensuing one by one after variable periods (months to years). Diagnostic tests and treatment are directed at each disorder as it is recognized because it is not possible to reliably predict or prevent any of these problems. Immunosuppressive drug therapy is not indicated for animals with these syndromes because the adverse effects of immunosuppressive therapy and the difficulty posed by suppression of the immune destruction of affected endocrine glands outweigh the potential benefits of such therapy.

# Clinical Pathology

The most consistent clinicopathologic findings in dogs with hypothyroidism are hypercholesterolemia and hypertriglyceridemia; the latter is identified as lipemia. Hypercholesterolemia is identified in approximately 75% of hypothyroid dogs, and the cholesterol concentration can exceed 1000 mg/

A and **B,** Eight-month-old female Giant Schnauzer litter mates. The dog on the left is normal, whereas the smaller dog on the right has congenital hypothyroidism (cretinism). Note the small stature; disproportionate body size; large, broad head; wide, square trunk; and short limbs in the cretin. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

В

dl. Although fasting hypercholesterolemia and hypertriglyceridemia can be associated with several other disorders (see Chapter 54), their presence in a dog with appropriate clinical signs is strong evidence for hypothyroidism.

A mild normocytic, normochromic, nonregenerative anemia (packed cell volume [PCV] of 28% to 35%) is a less consistent finding. Evaluation of red blood cell morphology may reveal an increase in the numbers of leptocytes (target cells), which develop as a result of increased erythrocyte membrane cholesterol loading. The white blood cell count is typically normal, and platelet counts are normal to increased.

A mild to moderate increase in lactate dehydrogenase; aspartate aminotransferase; alanine transaminase; alkaline phosphatase; and, rarely, creatine kinase activities may be identified but are extremely inconsistent findings and may not be directly related to the hypothyroid state. Mild hypercalcemia may be found in some dogs with congenital hypothyroidism. Results of urinalysis are usually normal. Polyuria, hyposthenuria, and urinary tract infections are not typical of hypothyroidism.

#### **DERMATOHISTOPATHOLOGIC FINDINGS**

Skin biopsies are often performed in dogs with suspected endocrine alopecia, especially if screening diagnostic tests (including tests to assess thyroid gland function) have failed to identify the cause. Nonspecific histologic changes are associated with various endocrinopathies, including hypothyroidism (see Table 49-5); histologic alterations that are claimed to be specific to hypothyroidism may also be seen, including vacuolated and/or hypertrophied arrector pili muscles, increased dermal mucin content, and thickened dermis. A variable inflammatory cell infiltrate may be present if a secondary pyoderma has developed.

#### **ULTRASONOGRAPHIC FINDINGS**

Ultrasound evaluation of the thyroid lobe may be helpful in differentiating dogs with hypothyroidism from euthyroid dogs with nonthyroidal illness causing low thyroid hormone test results. Lymphocytic thyroiditis and idiopathic atrophy eventually cause a decrease in the size and alterations in the echogenicity of the thyroid lobe. The thyroid lobe in euthyroid dogs is usually fusiform and triangular to oval in shape on longitudinal and transverse views, respectively; has a homogeneous echogenic pattern; is hyperechoic to isoechoic, compared with the echogenicity of the surrounding musculature; and has a hyperechoic capsule (Fig. 51-5). Although thyroid lobe shape is often similar between euthyroid and hypothyroid dogs, there is often a significant reduction in size and volume of the thyroid lobe in hypothyroid versus euthyroid dogs. In addition, the echogenicity of the thyroid lobe in hypothyroid dogs tends to be isoechoic to hypoechoic with hyperechoic foci, and the echogenic pattern often differs between thyroid lobes in the same dog. A direct correlation between size of the dog and size and volume of the normal thyroid gland may exist; the smaller the dog, the smaller the size and volume of the thyroid lobe (Fig. 51-6). This must be considered when evaluating thyroid lobe size in a dog with suspected hypothyroidism.

# **TESTS OF THYROID GLAND FUNCTION**Overview

Function of the thyroid gland is typically assessed by measuring baseline serum thyroid hormone concentrations. 3,5,3'5'-tetraiodothyronine (thyroxine  $[T_4]$ ) accounts for most of the thyroid hormone secreted by the thyroid gland, with only small quantities of 3,5,3'-triiodothyronine  $(T_3)$  and minor amounts of 3,3',5'-triiodothyronine (reverse  $T_3$   $[rT_3]$ ) released. Once secreted into the circulation, more than

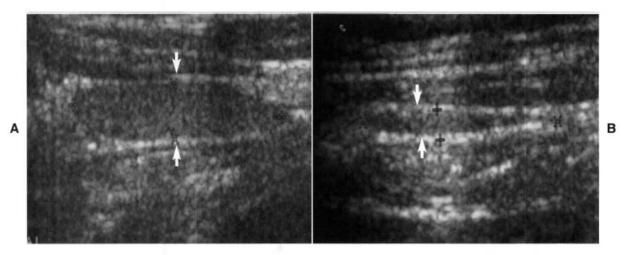

FIG 51-5

Note the significant reduction in the size of the thyroid lobe in the dog with hypothyroidism, compared with the thyroid lobe image from the healthy dog.

99% of  $T_4$  is bound to plasma proteins, which serves as a reservoir and buffer to maintain a steady concentration of free  $T_4$  ( $fT_4$ ) in the plasma. The unbound, or free,  $T_4$  is biologically active, exerts negative feedback inhibition on pituitary TSH secretion (see Fig. 51-1), and is capable of entering cells throughout the body (Fig. 51-7). Within the cell  $fT_4$  is

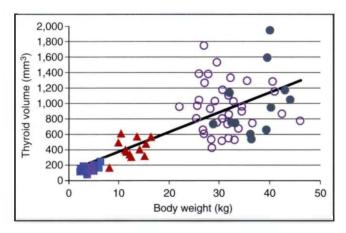

FIG 51-6

The relationship between total thyroid gland volume determined by ultrasound and body weight in 12 healthy Akitas (closed circles), 36 Golden Retrievers (open circles), 12 Beagles (triangles), and 12 Miniature and Toy Poodles (squares). Notice the positive correlation between body weight and size of the thyroid gland. (From Bromel C et al: Comparison of ultrasonographic characteristics of the thyroid gland in healthy small-, medium-, and large-breed dogs, Am J Vet Res 67:70, 2006.)

deiodinated to form either  $T_3$  or  $rT_3$ , depending on the metabolic demands of the tissues at that particular time.  $T_3$  is preferentially produced during normal metabolic states;  $rT_3$ , is biologically inactive.  $T_3$  is believed to be the primary hormone that induces physiologic effects.

All serum T<sub>4</sub>, both protein bound and free, comes from the thyroid gland. Therefore tests that measure the serum total and fT<sub>4</sub> concentrations, in conjunction with the serum TSH concentration, are currently recommended for the assessment of thyroid gland function in dogs suspected of having hypothyroidism. Serum T<sub>3</sub> concentration is a poor gauge of thyroid gland function because of its predominant location within cells and the minimal amount secreted by the thyroid gland in comparison with the amount of T<sub>4</sub> secreted (Fig. 51-8). Thus measurement of serum T<sub>3</sub>, free T<sub>3</sub>, and rT<sub>3</sub> concentration is not recommended for assessing thyroid gland function in dogs.

#### Baseline Serum T<sub>4</sub> Concentration

The baseline serum  $T_4$  concentration is the sum of the protein-bound and free levels circulating in the blood. Measurement of serum  $T_4$  concentration can be the initial screening test for hypothyroidism or be part of a thyroid panel containing  $T_4$ ,  $fT_4$ , TSH, an antibody test for lymphocytic thyroiditis, or some combination of these tests (Box 51-4).

Clinical chemistry laboratories currently use a radioimmunoassay (RIA) technique or enzyme immunoassay for measuring serum T<sub>4</sub>. Point-of-care ELISAs for measuring serum T<sub>4</sub> are also available, are economical, quick, and easy to perform, and allow the clinician to make recommendations the same day the dog (or cat) is evaluated. In a recent

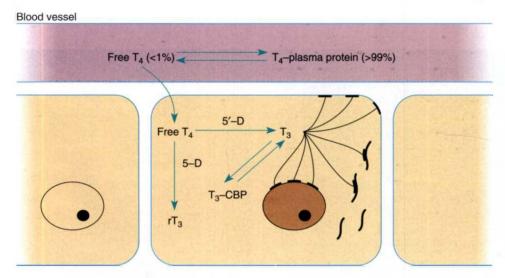

FIG 51-7

Intracellular metabolism of free T<sub>4</sub> to either T<sub>3</sub> or reverse T<sub>3</sub> by 5'- or 5-monodeiodinase, respectively. Intracellular T<sub>3</sub> formed from monodeiodination of free T<sub>4</sub> can interact with T<sub>3</sub> receptors on the cell membrane, mitochondria, or nucleus of the cell and stimulate the physiologic actions of thyroid hormone or bind to cytoplasmic binding proteins (CBP). The latter form an intracellular storage pool for T<sub>3</sub>. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

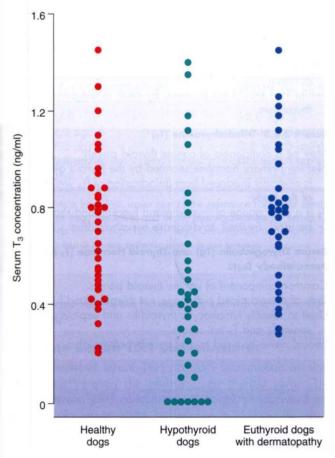

FIG 51-8
Baseline serum  $T_3$  concentrations in 35 healthy dogs, 35 dogs with hypothyroidism, and 30 euthyroid dogs with concurrent dermatopathy. Note the overlap in serum  $T_3$  concentrations among the three groups of dogs.

study serum  $T_4$  concentrations determined in dogs and cats by RIA, chemiluminescent enzyme immunoassay, and a point-of-care ELISA provided similar and consistent results (Kemppainen and Birchfield, 2006). For most laboratories the lower limit of the reference range for serum  $T_4$  in dogs is approximately 0.8 to 1.0  $\mu$ g/dl (10 to 13 nmol/L), although in some breeds the normal range may extend to as low as 0.5  $\mu$ g/dl (6 nmol/L) (see the discussion of breed variations, p. 740).

Theoretically, the interpretation of baseline serum  $T_4$  concentration should be straightforward in that dogs with hypothyroidism should have low values compared with the values in healthy dogs. Unfortunately, the serum  $T_4$  concentration range in hypothyroid dogs overlaps with that in healthy dogs and the serum  $T_4$  concentration can be suppressed by a variety of factors, most notably nonthyroidal illness and medications (Table 51-2). Clinicians often find it difficult to judge the effect that extraneous factors, especially concurrent illness, have on the serum  $T_4$  concentration. Because these variables can suppress a baseline serum  $T_4$  concentration to less than  $0.5 \mu g/dl$  in a euthyroid dog and hypothyroid dogs rarely have a serum  $T_4$  concentration

greater than 1.5 | g/dl, the serum T<sub>4</sub> concentration should be used to confirm normal thyroid gland function, not hypothyroidism per se (Table 51-3). A serum T<sub>4</sub> concentration greater than 1.5 µg/dl establishes normal thyroid gland function. The exception is a very small number (<1%) of hypothyroid dogs with lymphocytic thyroiditis that have serum T<sub>4</sub> autoantibodies that interfere with the RIA used to measure  $T_4$ . A serum  $T_4$  concentration less than 0.5  $\mu$  g/dl (6 nmol/L) suggests hypothyroidism, especially if the clinical signs, physical findings, and results of routine blood tests support the diagnosis and systemic illness is not present. The definitive diagnosis relies on response to trial therapy with levothyroxine in these dogs. Additional diagnostic tests of thyroid gland function are indicated if the serum T4 concentration is between 0.5 and 1.5 µg/dl; if the clinical signs, physical examination findings, and results of routine blood work are not strongly supportive of the disease; if severe systemic illness is present and the potential for the euthyroid sick syndrome is high; or if medications known to decrease serum T<sub>4</sub> concentration are being administered.

#### Baseline Serum fT<sub>4</sub> Concentration

Free T<sub>4</sub> is the nonprotein-bound fraction of T<sub>4</sub> circulating in blood and accounts for less than 1% of circulating T<sub>4</sub>. Currently, the most commonly used assays for measuring fT<sub>4</sub> in dogs are the Nichol's modified equilibrium dialysis assay (Antech Diagnostics, Inc.) and the Diasorin 2-step assay (Diasorin, Stillwater, Minn.). The modified equilibrium dialysis (ED) assay utilizes a short ED step to separate free from protein-bound T<sub>4</sub> followed by measurement of the free T<sub>4</sub> fraction by RIA. The Diasorin 2-step fT<sub>4</sub> assay uses two incubation temperatures (37° C for 20 minutes, then room temperature for 1 hour), not ED, to separate free and proteinbound T<sub>4</sub> followed by RIA to measure fT<sub>4</sub>. Preliminary studies suggest that results using the Diasorin 2-step RIA method are similar to results using the more traditional ED method. For most laboratories the lower limit of the reference range for serum fT<sub>4</sub> measured by ED and the 2-step RIA is approximately 0.5 to 0.8 ng/dl (6 to 10 pmol/L) in dogs.

Measurement of serum fT<sub>4</sub> is usually reserved for those dogs with suspected hypothyroidism and a nondiagnostic serum T<sub>4</sub> test result, severe concurrent illness, or both. ED assays for serum fT<sub>4</sub> concentration have comparable sensitivity but higher specificity than assays for serum T<sub>4</sub> concentration. Similar studies have not been reported for the 2-step RIA. Serum fT<sub>4</sub> is more resistant to the suppressive effects of nonthyroidal illness and medications than serum T<sub>4</sub>, although severe illness can cause serum fT<sub>4</sub> concentrations to decrease below 0.5 ng/dl. In addition, serum T<sub>4</sub> autoantibodies do not affect serum fT<sub>4</sub> results determined by ED. Interpretation of serum fT<sub>4</sub> test results is similar to that used to interpret serum T<sub>4</sub> test results (see Table 51-3). Serum fT<sub>4</sub> values greater than 1.5 ng/dl (20 pmol/L) are consistent with euthyroidism; values less than 0.5 ng/dl (6.5 pmol/L) are supportive of hypothyroidism, assuming the history, physical examination, and results of routine blood work are consistent with hypothyroidism and severe systemic illness is

#### Diagnostic Tests for Evaluating Thyroid Gland Function in the Dog

The decision to assess thyroid gland function should be based on results of the history, physical examination, and results of routine blood work (complete blood count, serum biochemistry panel, urinalysis).

#### Serum Thyroxine (T<sub>4</sub>)

Most commonly used initial screening test for hypothyroidism Normal serum  $T_4$  rules out hypothyroidism

Exception: T<sub>4</sub> autoantibodies that interfere with T<sub>4</sub> assay and cause spuriously high results (uncommon)

Low serum T<sub>4</sub> does not, by itself, confirm hypothyroidism Serum T<sub>4</sub> commonly suppressed below the reference range by nonthyroidal illness, drugs, and other factors in dogs with normal thyroid gland function

#### Serum Free Thyroxine (FT<sub>4</sub>) By Dialysis

Usually measured in dogs with nondiagnostic serum T<sub>4</sub> test results, severe nonthyroidal illness, or both; common component of canine thyroid panels

Normal serum fT<sub>4</sub> rules out hypothyroidism

Low serum fT<sub>4</sub> does not, by itself, confirm hypothyroidism; severe nonthyroidal illness and drugs can suppress serum fT<sub>4</sub> to below the reference range

#### Serum Thyrotropin (TSH)

Usually measured in dogs with nondiagnostic serum T<sub>4</sub> test results, severe nonthyroidal illness, or both; common component of canine thyroid panels

Provides additional evidence for or against the diagnosis of hypothyroidism

False positive and false negative serum TSH test results are common

Serum TSH should not be used, by itself, to diagnose hypothyroidism

#### Serum 3,5,3'-Triiodothyronine (T<sub>3</sub>)

May be a component of canine thyroid panels

Not the primary hormone secreted by the thyroid gland; T<sub>3</sub> is primarily produced from deiodination of fT<sub>4</sub> within cells of the body

T<sub>3</sub> is a poor gauge of thyroid gland function and should not be used, by itself, to diagnose hypothyroidism

#### Serum Thyroglobulin (Tg) and Thyroid Hormone ( $T_3$ and $T_4$ ) Autoantibody Tests

Common component of canine thyroid panels
Tests of thyroid gland pathology, not thyroid gland function
Used to identify lymphocytic thyroiditis and explain unusual serum T<sub>4</sub> and T<sub>3</sub> test results

Should never be used to diagnose hypothyroidism

**TABLE 51-2**

Increased or decreased $T_4$ ; no effect on free $T_4$ or TSH

TSH, Thyroid-stimulating hormone.

<sup>\*</sup>There is a direct correlation between the severity and systemic nature of the illness and suppression of serum T<sub>4</sub> and free T<sub>4</sub> concentrations.

**TABLE 51-3** 

Interpretation of Baseline Serum Thyroxine ( $T_4$ ) and Free Thyroxine ( $fT_4$ ) Concentration in Dogs with Suspected Hypothyroidism\*

SERUM T4 CONCENTRATION	SERUM FT4 CONCENTRATION	PROBABILITY OF HYPOTHYROIDISM
>2.0 µg/dl	>2.0 ng/dl	Very unlikely
1.5 to 2.0 μg/dl	1.5 to 2.0 ng/dl	Unlikely
0.8 to 1.5 μg/dl	0.8 to 1.5 ng/dl	Unknown
0.5 to 0.8 μg/dl	0.5 to 0.8 ng/dl	Possible
<0.5 μg/dl	<0.5 ng/dl	Very likely <sup>†</sup>

<sup>\*</sup>Interpretation based on lower end of the reference range for serum  $T_4$  and  $fT_4$  being 0.8  $\mu$ g/dl and 0.8  $\eta$ g/dl, respectively, without regard for breed of dog. The lower end of the reference range for serum  $T_4$  and  $fT_4$  may be as low as 0.5  $\mu$ g/dl and 0.5  $\eta$ g/dl, respectively, for some breeds such as sight hounds (e.g., Greyhounds) and Nordic breeds (e.g., Siberian Huskies).

not present; and values between 0.5 and 1.5 ng/dl are not diagnostic.

#### **Baseline Serum TSH Concentration**

Measurement of serum TSH provides information on the interaction between the pituitary and thyroid gland. In theory, serum TSH concentration should be increased in dogs with hypothyroidism. In dogs serum TSH can be measured using immunoradiometric, chemiluminescent immunometric, and enzyme immunometric assays. In one study the highest precision for canine TSH analysis was obtained with the chemiluminescent assay, although the correlation between the three assays for measuring canine serum TSH was satisfactory (Marca et al., 2001). Most clinical laboratories use a serum TSH concentration of 0.6 ng/ml as the upper limit of the reference range. The lower limit of the reference range is currently below the sensitivity of these assays; differentiation between low and normal serum TSH concentrations is not possible.

Measurement of serum TSH concentration is usually reserved for dogs with suspected hypothyroidism and nondiagnostic serum T4 test results. A serum TSH concentration greater than 0.6 ng/ml is consistent with hypothyroidism. Unfortunately, serum TSH concentrations can be normal in dogs with histologically confirmed hypothyroidism and increased in euthyroid dogs with concurrent nonthyroidal illness or dogs receiving drugs such as phenobarbital (Fig. 51-9). In most studies the sensitivity and specificity of the TSH assay has ranged from 63% to 87% and 82% to 93%, respectively. Serum TSH test results should always be interpreted in conjunction with results of serum T4, fT4, or both and should not be used alone in the diagnosis of hypothyroidism. Serum TSH test results increase the likelihood of euthyroidism or hypothyroidism when results are consistent with results of serum T4 and fT4 tests. A normal serum T4 and fT4 concentration and increased serum TSH concentration occur in the early stages of primary hypothyroidism in humans. Although similar thyroid hormone and TSH test results have been identified in dogs, it is not known what percentage of these dogs progress to clinical hypothyroidism. Clinical signs of hypothyroidism are usually not evident in these dogs, presumably because serum  $T_4$  and  $fT_4$  concentrations are in the reference range. Treatment with levothyroxine is not indicated. Rather, assessment of thyroid gland function should be repeated in 3 to 6 months, especially if antibody tests for lymphocytic thyroiditis are positive. If progressive destruction of the thyroid gland is occurring, serum  $T_4$  and  $fT_4$  concentrations will gradually decrease and clinical signs will eventually develop.

#### **TSH and TRH Stimulation Tests**

TSH and TRH stimulation tests evaluate the thyroid gland's responsiveness to exogenous TSH and TRH administration, respectively. The primary advantage of these tests is that they help differentiate between hypothyroidism and nonthyroidal illness in dogs with low serum  $T_4$  and  $fT_4$  concentrations. Unfortunately, TRH for injection is currently not available. Recombinant human TSH (rhTSH) for injection is effective in stimulating thyroid hormone secretion in dogs but is not available at a reasonable cost. The current TSH stimulation protocol for dogs is 75 ug of rhTSH per dog administered intravenously or intramuscularly and blood for serum T4 concentration obtained before and 6 hours after rhTSH administration. In a euthyroid dog serum T<sub>4</sub> concentration should be ≥ 2.5 µg/dl (30 nmol/L) 6 hours after rhTSH administration and the 6-hour post-rhTSH serum T4 concentration should be ≥1.5 times the baseline serum T<sub>4</sub> concentration. Reconstituted rhTSH can be stored at 4° C for 4 weeks and at -20° C for 8 weeks without loss of biological activity.

#### **Antibody Tests for Lymphocytic Thyroiditis**

Circulating thyroglobulin (Tg) and thyroid hormone ( $T_3$  and  $T_4$ ) autoantibodies correlate with the presence of lymphocytic thyroiditis in dogs. Tests for the presence of Tg,  $T_3$ , and  $T_4$  autoantibodies in the serum of dogs can be used to identify lymphocytic thyroiditis, to explain unusual serum

<sup>&</sup>lt;sup>†</sup>Assuming that a severe systemic illness is not present.

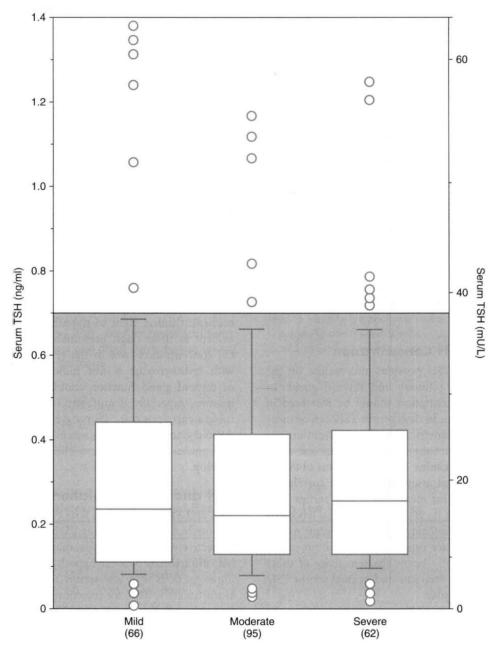

FIG 51-9

Box plots of serum concentrations of thyrotropin (TSH) in 223 dogs with nonthyroidal disease stratified according to severity of disease. For each box plot T-bars represent the main body of data, which in most instances is equal to the range. Each box represents an interquartile range (twenty-fifth to seventy-fifth percentile). The horizontal bar in each box is the median. Open circles represent outlying data points. Numbers in parentheses indicate the numbers of dogs in each group. Shaded area is the normal range. (From Kantrowitz LB et al: Serum total thyroxine, total triiodothyronine, free thyroxine, and thyrotropin concentrations in dogs with nonthyroidal disease, J Am Vet Med Assoc 219:765, 2001.)

 $T_4$  test results, and possibly to serve as a genetic screening test for hypothyroidism caused by lymphocytic thyroiditis. Autoantibodies predominantly develop against Tg.  $T_3$  and  $T_4$  are haptens and not antigenic by themselves. Tg is the protein that provides the antigenic stimulus. Because  $T_3$  and  $T_4$  are attached to the Tg molecule, autoantibodies develop

against them as well. Dogs with  $T_3$  and  $T_4$  autoantibodies typically have autoantibodies against Tg, but the converse is not true. As such, the better screening test for lymphocytic thyroiditis is the Tg autoantibody test. ELISAs for detection of Tg autoantibodies are sensitive and specific for identification of Tg autoantibodies in dogs and are commercially

available. Results are reported as negative, positive, and inconclusive.

A positive Tg autoantibody test suggests the possibility of lymphocytic thyroiditis but does not provide information on the severity or progressive nature of the inflammatory process. Tg autoantibody is not a thyroid function test. Positive results increase the suspicion for hypothyroidism if serum  $T_4$  and  $fT_4$  concentrations are low but have no bearing on generation of clinical signs if serum T4 and fT4 concentrations are normal. Tg autoantibodies should not be used alone in the diagnosis of hypothyroidism. Dogs with confirmed hypothyroidism can be negative and euthyroid dogs can be positive for Tg autoantibodies. Identification of Tg autoantibodies would support hypothyroidism caused by lymphocytic thyroiditis if the dog has clinical signs, physical findings, and thyroid hormone test results consistent with the disorder. Positive serum T4 and T3 autoantibody test results are interpreted in a similar manner.

The value of serum Tg autoantibodies as a marker for eventual development of hypothyroidism remains to be clarified. A 1-year prospective study found that approximately 20% of 171 dogs with positive Tg autoantibody and normal  $f\Gamma_4$  and TSH test results developed changes in  $f\Gamma_4$ , TSH, or both test results consistent with hypothyroidism; 15% reverted to a negative Tg autoantibody test with no change in  $f\Gamma_4$  and TSH test results; and 65% remained Tg autoantibody positive or had an inconclusive result with no change in  $f\Gamma_4$  and TSH test results 1 year later (Graham et al., 2001). Currently, a positive Tg autoantibody test is considered suggestive of lymphocytic thyroiditis and supports retesting thyroid gland function in 3 to 6 months.

Testing for serum T<sub>4</sub> or Tg autoantibodies is indicated in dogs with unusual serum T4 values. T4 autoantibodies may interfere with the RIAs used to measure serum T4 concentrations, which thereby yield spurious and thus unreliable values. The type of interference depends on the separation system used in the RIA. Falsely low results are obtained if nonspecific separation methods are used (e.g., ammonium sulfate, activated charcoal); falsely increased values are obtained if single-step separation systems using antibodycoated tubes are used. Fortunately, spurious T4 values resulting from clinically relevant concentrations of thyroid hormone antibody account for less than 1% of such results from commercial endocrine laboratories. Serum fT4 measured using an ED technique is not affected by T4 autoantibodies and should be evaluated in lieu of serum T4 in dogs suspected of having  $T_4$  autoantibodies.

# FACTORS AFFECTING THYROID GLAND FUNCTION TESTS

There are many factors that affect baseline thyroid hormone and endogenous TSH concentrations (see Table 51-2). Unfortunately, most of these factors decrease baseline thyroid hormone concentrations and may increase endogenous TSH in euthyroid dogs, potentially causing misdiagnosis of hypothyroidism if the clinician accepts the results out of context.

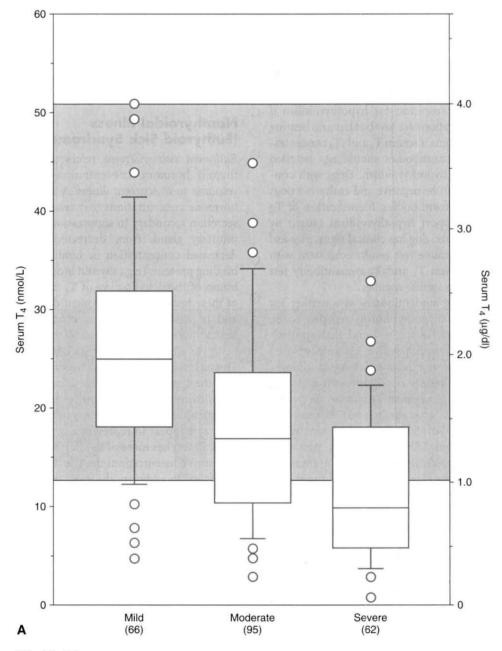

The most common factors that result in lower baseline thyroid hormone concentrations in euthyroid dogs are non-thyroidal illness (i.e., euthyroid sick syndrome), drugs (especially glucocorticoids, phenobarbital, and sulfonamide antibiotics; see Table 51-2), and variation in the reference range between breeds (most notably sight hounds).

#### Nonthyroidal Illness (Euthyroid Sick Syndrome)

Euthyroid sick syndrome refers to suppression of serum thyroid hormone concentrations in euthyroid dogs in response to concurrent illness. A decrease in serum thyroid hormone concentrations may result from a decline in TSH secretion secondary to suppression of the hypothalamus or pituitary gland, from decreased synthesis of T4, from decreased concentration or binding affinity of circulating binding proteins (e.g., thyroid binding globulin), from inhibition of the deiodination of T<sub>4</sub> to T<sub>3</sub>, or any combination of these factors. The subsequent decrease in serum total T<sub>4</sub> and, in many cases, fT<sub>4</sub> concentrations is believed to represent a physiologic adaptation by the body, with the purpose being to decrease cellular metabolism during periods of illness. It is not indicative of hypothyroidism, per se. Generally, the type and magnitude of most alterations in serum thyroid hormone concentrations are not unique to a specific disorder but reflect the severity of the illness or the catabolic state and appear to represent a continuum of changes. Systemic illness has more of an effect in lowering serum thyroid hormone concentrations than do, for example, dermatologic disorders. In addition, the more severe the systemic illness, the more suppressive the effect on the serum thyroid hormone concentration (Fig. 51-10).

Unfortunately, euthyroid dogs with concurrent illness can have serum T<sub>4</sub> concentrations that often fall between 0.5 and 1.0 µg/dl, and with severe illness (e.g., cardiomyopathy, severe anemia) these concentrations can be less than 0.5 µg/ dl. Alterations in serum concentrations of fT4 and TSH are more variable and probably depend in part on the pathophysiologic mechanisms involved in the illness. In general, serum fT4 concentrations tend to be decreased in dogs with concurrent illness but to a lesser extent than total T<sub>4</sub> concentrations. However, fT<sub>4</sub> concentrations can be less than 0.5 ng/ dl if severe illness is present. TSH concentrations may be normal or increased depending, in part, on the effect of the concurrent illness on  $f\Gamma_4$  concentrations and on pituitary function. If pituitary function is suppressed, TSH concentrations will be in the normal range or undetectable. If pituitary response to changes in fT4 concentration is not affected by the concurrent illness, TSH concentrations will increase in response to a decrease in fT<sub>4</sub>. Serum TSH concentrations can easily exceed 1.0 ng/ml in dogs with euthyroid sick

Treatment of euthyroid sick syndrome should be aimed at the concurrent illness. The serum thyroid hormone concentrations return to normal once the concurrent illness is eliminated. Treatment of euthyroid sick syndrome with sodium levothyroxine is not recommended.

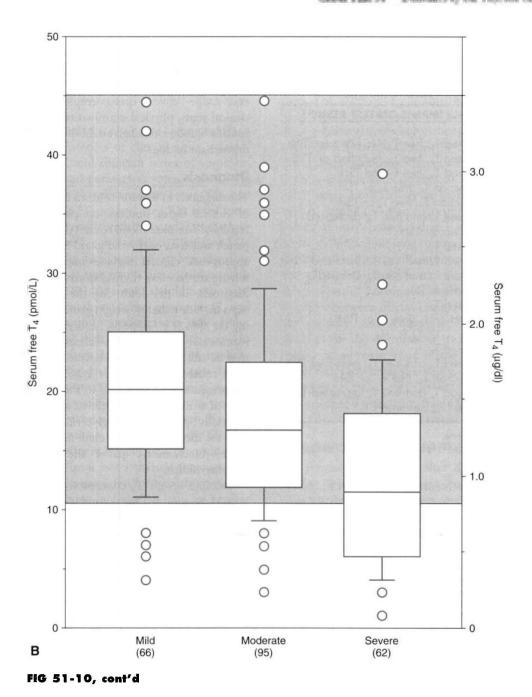

**FIG 51-10** Box plots of serum total  $T_4$  (A) and free  $T_4$  (B) concentrations in 223 dogs with nonthyroidal disease stratified according to severity of disease. See Fig. 51-9 for explanation. (From Kantrowitz LB et al: Serum total thyroxine, total triiodothyronine, free thyroxine, and thyrotropin concentrations in dogs with nonthyroidal disease, *J Am Vet Med Assoc* 219:765, 2001.)

#### Drugs

Clinical knowledge of the effect, if any, of various drugs and hormones on serum thyroid hormone and TSH concentrations in dogs is expanding as investigators continue to examine the interplay between medications and thyroid hormone test results (Table 51-4). As a general rule, any drug should be suspected of affecting thyroid hormone test results, especially if the history, clinical signs, and clinicopathologic

abnormalities do not support a diagnosis of hypothyroidism. Glucocorticoids, phenobarbital and sulfonamides are the most commonly used drugs known to affect serum thyroid hormone test results.

**Glucocorticoids.** Glucocorticoids cause a decrease in serum  $T_4$  and  $fT_4$  concentrations. Serum TSH concentration is variable but usually within the reference range. The magnitude and duration of suppression of serum thyroid

hormone concentrations depend on the type of glucocorticoid, dosage, route of administration, and duration of glucocorticoid administration. The higher the dosage, the longer the administration, and the more potent the glucocorticoid administered, the more severe the suppression of serum thyroid hormone concentrations. If glucocorticoids have been administered in the recent past, assay of serum thyroid hormone concentrations should be delayed or must be interpreted carefully. Ideally, glucocorticoids should be discontinued and serum thyroid hormone and TSH concentrations

Typically, the administration of exogenous glucocorticoids does not result in clinical signs of hypothyroidism. The

assessed 4 to 8 weeks later.

exception are dogs receiving relatively high dosages of glucocorticoids for prolonged periods to treat chronic steroidresponsive disorders (e.g., immune-mediated diseases). In these dogs glucocorticoid-induced secondary hypothyroidism may become clinical and require treatment with synthetic levothyroxine.

**Phenobarbital.** In dogs phenobarbital treatment at therapeutic dosages decreases serum  $T_4$  and  $fT_4$  concentrations into the range consistent with hypothyroidism. A delayed increase in the serum TSH concentration may occur secondary to loss of negative feedback as serum  $T_4$  and  $fT_4$  concentrations decline. Increased serum TSH concentrations quickly return to the reference range after discontinu-

Drugs that May Affect Baseline Serum Thyroid Hormone Function Test Results in the Dog

#### DRUG **POSSIBLE IMPACT ON TEST RESULTS** Aspirin Decreased T<sub>4</sub>, free T<sub>4</sub>; No effect on TSH Clomipramine Decreased $T_4$ , free $T_4$ ; No effect on TSH Carprofen Decreased T<sub>4</sub>, free T<sub>4</sub> and TSH Deracoxib No effect on $T_4$ , free $T_4$ or TSH Etodolac No effect on T<sub>4</sub>, free T<sub>4</sub> or TSH Glucocorticoids Decreased T<sub>4</sub> and free T<sub>4</sub>; decreased or no effect on TSH Furosemide Decreased T<sub>4</sub> Methimazole Decreased T<sub>4</sub> and free T<sub>4</sub>; increased TSH Decreased T<sub>4</sub> and free T<sub>4</sub>; Delayed **Phenobarbital** increase in TSH Phenylbutazone Decreased T<sub>4</sub> No effect on T<sub>4</sub>, free T<sub>4</sub> or TSH Potassium bromide **Progestagens** Decreased T<sub>4</sub> Propylthiouracil Decreased T<sub>4</sub> and free T<sub>4</sub>; increased TSH Cephalexine No effect on T<sub>4</sub>, free T<sub>4</sub>, or TSH Sulfonamides Decreased T<sub>4</sub> and free T<sub>4</sub>; increased TSH **Ipodate** Increased T<sub>4</sub>, decreased T<sub>3</sub>

TSH, Thyroid-stimulating hormone.

ation of phenobarbital treatment, whereas serum  $T_4$  and  $fT_4$  concentrations may take up to 4 weeks to return to pretreatment values. Potassium bromide treatment does not seem to have a significant effect on serum  $T_4$ ,  $fT_4$  and TSH concentrations in dogs.

**Sulfonamide antibiotics.** A decrease in serum  $T_4$  and  $fT_4$  and an increase in TSH concentrations have been documented in dogs treated with sulfonamides (e.g., sulfamethoxazole, sulfadiazine). Serum  $T_4$  concentrations can decrease into the hypothyroid range within 1 to 2 weeks and serum TSH concentrations can increase above the reference range within 2 to 3 weeks after initiating sulfonamide therapy. Clinical signs of hypothyroidism can develop with chronic sulfonamide administration. The increase in the serum TSH concentration occurs secondary to loss of negative feedback as serum  $T_4$  and  $fT_4$  concentrations decline and can lead to thyroid hyperplasia and goiter. Alterations in results of thyroid gland function tests may resolve within 1 to 2 weeks or last as long as 8 to 12 weeks after cessation of the antibiotic.

#### **Breed Variations**

Current reference ranges were established in large populations of dogs without regard for breed. It is now recognized that the reference range for serum  $T_4$  and  $fT_4$  concentration but not TSH concentration is lower in sight hounds, most notably Greyhounds, and Northern breeds such as the Siberian Husky and may be lower in other breeds as well. The lower end of the reference range for serum  $T_4$  and  $fT_4$  in these

breeds may be as low as  $0.4 \,\mu\text{g/dl}$  and  $0.4 \,\text{ng/dl}$ , respectively. Serum  $T_4$  and  $fT_4$  concentrations that are consistent with hypothyroidism according to standard reference ranges may actually be normal in these breeds. Differences in the reference range between breeds emphasizes the importance of clinical signs, physical examination findings, and results of routine blood work when establishing the diagnosis of hypothyroidism in dogs.

#### Diagnosis

The diagnosis of hypothyroidism is based on a combination of clinical signs; findings on physical examination; and results of complete blood count (CBC), serum biochemistry panel, and tests of thyroid gland function. The presence of appropriate clinical signs is imperative, especially when relying on baseline thyroid hormone concentrations for a diagnosis. In the adult dog the most consistent clinical signs include lethargy, weight gain, and abnormalities affecting the skin (e.g., alopecia, seborrhea, pyoderma) and neuromuscular system (e.g., weakness). Other organ systems may be affected by thyroid hormone deficiency, but clinical signs related to these other systems are rarely the reason for presentation of the dog to the veterinarian. Identification of a mild nonregenerative anemia on the CBC and especially lipemia (hypertriglyceridemia) in the blood sample and an increased serum cholesterol concentration on a serum biochemistry panel adds further evidence for hypothyroidism.

Baseline serum T<sub>4</sub> concentration is often used as the initial screening test for thyroid gland function. It is important to remember that serum T4 concentrations can be suppressed by a variety of factors, most notably nonthyroidal illness and medications such as prednisone and phenobarbital. As such, measurement of the serum T<sub>4</sub> concentration should be used to confirm normal thyroid gland function, not hypothyroidism per se. A normal serum T4 concentration establishes normal thyroid gland function unless serum  $T_4$  autoantibodies are present and interfering with the assay. A low serum T<sub>4</sub> concentration (ideally less than 0.5 µg/dl [6 nmol/L]) in conjunction with hypercholesterolemia and clinical signs strongly suggestive of the disease supports the diagnosis of hypothyroidism, especially if systemic illness is not present. The definitive diagnosis must then rely on response to trial therapy with synthetic levothyroxine. Additional tests of thyroid gland function are warranted if the serum T<sub>4</sub> concentration is less than 0.8 to 1.0 μg/dl but clinical signs and physical examination findings are not strongly supportive of the disease and hypercholesterolemia is not present, if severe systemic illness is present and the potential for the euthyroid sick syndrome is high, or if medications known to decrease serum T<sub>4</sub> concentration are being administered.

Evaluation of a thyroid panel that includes serum  $T_4$ ,  $fT_4$ , TSH, and Tg autoantibody provides a more informative analysis of the pituitary-thyroid axis and thyroid gland function, can be used as the initial screening test for hypothyroidism, and should be used when serum  $T_4$  concentration alone

fails to establish the diagnosis. Low serum  $T_4$  and  $fT_4$ , and increased serum TSH concentrations in a dog with appropriate clinical signs and clinicopathologic abnormalities strongly support the diagnosis of hypothyroidism. Concurrent presence of Tg autoantibodies suggests lymphocytic thyroiditis as the underlying etiology.

Unfortunately, discordant test results are common. When this occurs, the appropriateness of clinical signs, clinicopathologic abnormalities, and clinician index of suspicion become the most important parameters when determining whether to treat the dog with levothyroxine. Serum fl'<sub>4</sub> concentration measured using ED or the 2-step RIA is the most accurate test of thyroid gland function and carries the highest priority, followed by serum T<sub>4</sub> concentration. Results of TSH concentration increase the likelihood of euthyroidism or hypothyroidism when TSH test results are consistent with results of serum fT4, but TSH test results should not be used as the sole indicator of hypothyroidism. Low serum fI4 and normal TSH test results occur in approximately 20% of dogs with hypothyroidism, and high TSH test results occur in euthyroid dogs with nonthyroidal illness and with medications such as phenobarbital and sulfonamides (see Tables 51-2 and 51-4). Normal serum fT<sub>4</sub> and high TSH may suggest early compensated hypothyroidism, but one has to wonder why clinical signs would develop when the serum fT4 concentration is normal. Positive Tg autoantibody findings merely suggest the possibility of lymphocytic thyroiditis; Tg autoantibody determination is not a thyroid function test. Positive results increase the suspicion for hypothyroidism if serum  $T_4$  or  $fT_4$  concentrations are low but have no bearing on the generation of clinical signs if serum T<sub>4</sub> and fT<sub>4</sub> concentrations are normal. When faced with discordant test results, the clinician must decide whether to initiate trial therapy with synthetic levothyroxine or repeat the tests sometime in the future—a decision that I usually base on the appropriateness of clinical signs and results of the fT<sub>4</sub> measured using ED or the 2-step RIA.

Admittedly, interpretation of serum T4, fT4, and TSH concentrations is not always simple. Because of the expense and frustration of working with tests that are not always reliable, many veterinarians and some clients prefer trial therapy as a diagnostic test. Trial therapy should be done only when thyroid hormone supplementation does not pose a risk to the patient. Response to trial therapy with sodium levothyroxine is nonspecific. A dog that has a positive response to therapy either has hypothyroidism or "thyroid-responsive disease." Because of its anabolic nature, thyroid supplementation can create an effect in a dog without thyroid dysfunction, especially regarding quality of the haircoat. Therefore, if a positive response to trial therapy is observed, thyroid supplementation should be gradually discontinued once clinical signs have resolved. If clinical signs recur, hypothyroidism is confirmed and the supplement should be reinitiated. If clinical signs do not recur, a thyroid-responsive disorder or a beneficial response to concurrent therapy (e.g., antibiotics, flea control) should be suspected.

# DIAGNOSIS IN A PREVIOUSLY TREATED DOG

Occasionally, a clinician wants to determine if a dog receiving thyroid hormone supplementation is in fact hypothyroid. The exogenous administration of thyroid hormone, either T4 or T3, will suppress pituitary TSH secretion and cause pituitary thyrotroph atrophy and subsequently thyroid gland atrophy in a healthy cuthyroid dog. Serum T<sub>4</sub>, fT<sub>4</sub>, and TSH concentrations are decreased or undetectable; the severity of the decrease is dependent on the severity of thyroid gland atrophy induced by the thyroid supplement. Serum T<sub>4</sub> and fT<sub>4</sub> results are often suggestive of hypothyroidism, even in a previously euthyroid dog, if testing is performed within a month of discontinuing treatment. Thyroid hormone supplementation must be discontinued and the pituitary-thyroid axis allowed to regain function before meaningful baseline serum thyroid hormone concentrations can be obtained. The time between discontinuation of thyroid hormone supplementation and acquisition of meaningful test results depends on the duration of treatment, the dose and frequency of administration of the thyroid hormone supplement, and individual variability. As a general rule, thyroid hormone supplements should be discontinued for a minimum of 4 weeks, preferably 6 to 8 weeks, before thyroid gland function is critically assessed.

#### DIAGNOSIS IN PUPPIES

An approach similar to that discussed in the previous section is used to diagnose congenital hypothyroidism. However, serum TSH concentrations are dependent on the etiology. TSH concentrations will be increased in dogs with primary dysfunction of the thyroid gland (e.g., iodine organification defect) and an intact hypothalamic-pituitary-thyroid gland axis. TSH concentrations will be within the normal range or undetectable in dogs with pituitary or hypothalamic dysfunction as the cause of the hypothyroidism.

#### Treatment

# THERAPY WITH SODIUM LEVOTHYROXINE (SYNTHETIC T4)

The initial treatment and monitoring recommendations are summarized in Box 51-5. Synthetic levothyroxine is the treatment of choice for hypothyroidism. Its administration orally should result in normal serum concentrations of T<sub>4</sub>, T<sub>3</sub>, and TSH, which attests to the fact that these products can be converted to the more metabolically active T<sub>3</sub> by peripheral tissues. A sodium levothyroxine product approved for use in dogs is recommended. Liquid and tablet formulations are effective. The initial dosage is 0.02 mg/kg body weight (0.1 mg/10 lb) with a maximum initial dose of 0.8 mg. Twice-daily administration is recommended initially unless the levothyroxine product has been specifically formulated for once-daily administration. Because of the variability in its absorption and metabolism, the dose and frequency may have to be adjusted before a satisfactory clinical response is

BOX 51-5

Recommendations for the Initial Treatment and Monitoring of Hypothyroidism in Dogs

#### **Initial Treatment**

Use a synthetic levothyroxine product approved for use in dogs.

Tablet and liquid formulations of levothyroxine are effective.

The initial dosage per administration should be 0.02~mg/kg (20  $\mu g/kg$ ) of body weight, with a maximum initial dose of 0.8~mg.

The initial frequency of administration is every 12 hours unless the levothyroxine product has been specifically formulated for once-daily administration.

#### **Initial Monitoring**

Response to treatment should be critically evaluated 4 to 8 weeks after initiating treatment.

Serum T<sub>4</sub> and TSH concentrations should be measured 4 to 6 hours after administration of levothyroxine.

Serum  $T_4$  should be in the reference range or increased. Serum TSH concentration should be in the reference range.

Measuring serum T<sub>4</sub> concentration immediately before levothyroxine administration (i.e., trough level) is optional but is recommended if levothyroxine is being given once a day.

The trough concentration of serum  $T_4$  should be in the reference range.

TSH, Thyroid-stimulating hormone.

observed; this variability is one reason for monitoring therapy in dogs.

# RESPONSE TO SODIUM LEVOTHYROXINE THERAPY

Thyroid hormone supplementation should be continued for a minimum of 4 weeks before critically evaluating the effectiveness of treatment. With appropriate therapy all clinical signs and clinicopathologic abnormalities associated with hypothyroidism are reversible. Improvement in mental alertness and activity usually occurs within the first week of treatment; this is an important early indicator that the diagnosis of hypothyroidism was correct. Although some hair regrowth usually occurs within the first month in dogs with endocrine alopecia, it may take several months for complete regrowth and a marked reduction in hyperpigmentation of the skin to occur. Initially, the haircoat may worsen as large amounts of hair in the telogen stage of the hair cycle are shed. Improvement in neurologic manifestations is usually evident within days of initiating treatment; complete resolution of neurologic signs is unpredictable and may take 4 to 8 weeks or longer of treatment before it occurs.

BOX 51-6

Potential Reasons for Poor Clinical Response to Treatment with Sodium Levothyroxine (Synthetic T<sub>4</sub>)

Client compliance problems
Use of inactivated or outdated product
Inappropriate levothyroxine dose
Inappropriate frequency of administration

Low tablet strength\*
Poor bioavailability (e.g., poor gastrotintestinal tract

absorption)
Inadequate time for clinical response to occur
Incorrect diagnosis of hypothyroidism

\* Tablet strength refers to actual amount of active drug in tablet, as opposed to the stated amount.

# FAILURE TO RESPOND TO SODIUM LEVOTHYROXINE THERAPY

Problems with levothyroxine therapy should be suspected if clinical improvement is not seen by 8 weeks after initiating therapy. An inappropriate diagnosis of hypothyroidism is the most obvious. Hyperadrenocorticism can be mistaken for hypothyroidism if other clinical signs (e.g., polyuria, polydipsia) commonly associated with hyperadrenocorticism are not present because of the suppressive effects of cortisol on serum thyroid hormone concentrations (see p. 738). Failure to recognize the impact of concurrent illness on thyroid hormone test results is another common reason for misdiagnosing hypothyroidism. Concurrent disease (e.g., allergic skin disease, flea hypersensitivity) is common in dogs with hypothyroidism and may affect the clinical impression of response to levothyroxine therapy if the disease is not recognized. Other possible reasons for a poor response to therapy are listed in Box 51-6. Whenever a dog shows a poor response to levothyroxine therapy, the history, physical examination findings, and diagnostic test results that prompted the initiation of levothyroxine therapy should be critically reevaluated and serum thyroid hormone concentrations measured.

#### THERAPEUTIC MONITORING

Therapeutic monitoring includes evaluation of the clinical response to levothyroxine treatment, measurement of serum  $T_4$  and TSH concentrations before or after levothyroxine administration, or both. These concentrations should be measured 4 weeks after initiating therapy, whenever signs of thyrotoxicosis develop, or in the event that there has been minimal or no response to therapy. Concentrations should also be measured 2 to 4 weeks after an adjustment in levothyroxine therapy in dogs showing a poor response to treatment.

Serum T<sub>4</sub> and TSH concentrations are typically evaluated 4 to 6 hours after the administration of levothyroxine in dogs receiving the medication twice daily and just before and 4 to

6 hours after administration in dogs receiving it once a day. Measurement of serum fT<sub>4</sub> can be done in lieu of measuring T<sub>4</sub> but is more expensive and probably does not offer additional information except in dogs with T<sub>4</sub> autoantibodies. The presence of thyroid hormone autoantibodies does not interfere with the physiologic actions of levothyroxine.

Ideally, the serum  $T_4$  concentration should be between 1.5 and 4.5 µg/dl when measured 4 to 6 hours after thyroid hormone administration and the TSH concentration should be in the reference range. Postdosing serum T<sub>4</sub> concentrations are frequently above the reference range. The finding of an increased postdosing serum T4 concentration is not an absolute indication to reduce the dose of levothyroxine, especially if there are no clinical signs of thyrotoxicosis. However, a reduction in the dose is recommended whenever serum T<sub>4</sub> concentrations exceed 6.0 μg/dl. Postdosing serum  $T_4$  concentrations may also be less than 1.5  $\mu$ g/dl. An increase in the dose or frequency of administration of levothyroxine is indicated if clinical manifestations of hypothyroidism persist, the serum TSH concentration remains increased, or both, but it is not necessarily indicated if the clinical response to treatment is good and the serum TSH concentration is in

the reference range. Postdosing serum  $T_4$  and TSH concentrations and recommendations for changes in therapy are given in Fig. 51-11.

#### **THYROTOXICOSIS**

Thyrotoxicosis may develop in dogs receiving excessive amounts of levothyroxine; in dogs in which the plasma halflife for levothyroxine is inherently prolonged, especially in those receiving levothyroxine twice daily; and in dogs with impaired metabolism of levothyroxine (e.g., concurrent renal or hepatic insufficiency). Rarely, thyrotoxicosis develops in a dog given minute amounts of levothyroxine. The reason for this marked sensitivity to the hormone is not known. Diagnosis of thyrotoxicosis is based primarily on presence of clinical signs, which include panting, nervousness, aggressive behavior, polyuria, polydipsia, polyphagia, and weight loss. Documenting increased serum T<sub>4</sub> and fT<sub>4</sub> and undetectable serum TSH concentrations supports the diagnosis. However, serum T4 and fT4 concentrations can occasionally be within the reference range in a dog with signs of thyrotoxicosis and are commonly increased in dogs with no signs of thyrotoxicosis. Adjustments in the dose or fre-

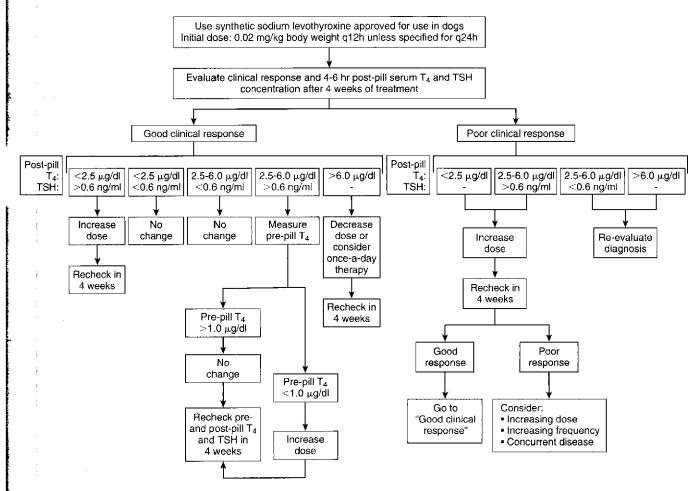

FIG 51-11
Initial therapeutic approach and monitoring recommendations for dogs with hypothyroidism.

quency of administration of levothyroxine, or both measures, are indicated if clinical signs of thyrotoxicosis develop in a dog receiving thyroid hormone supplements. Supplementation should be discontinued for a few days if clinical signs are severe. Signs of thyrotoxicosis should resolve within I to 3 days if they are due to the thyroid medication and the adjustment in treatment has been appropriate.

#### **Prognosis**

The prognosis for adult dogs with primary hypothyroidism that are receiving appropriate therapy is excellent. The prognosis for puppies with hypothyroidism (i.e., cretinism) is guarded and depends on the severity of skeletal and joint abnormalities at the time treatment is initiated. Although many of the clinical signs resolve with therapy, musculoskeletal problems, especially degenerative osteoarthritis, may develop owing to abnormal bone and joint development. The prognosis for dogs with secondary hypothyroidism caused by congenital malformation of the pituitary gland (i.e., pituitary dwarfism) is guarded to poor because of the multiple problems that develop in early life (see Chapter 49). The prognosis for dogs with acquired secondary hypothyroidism caused by suppression of pituitary function by medications (e.g., glucocorticoids) is excellent, although treatment with levothyroxine may be necessary if the medication can not be discontinued. The prognosis for dogs with acquired secondary hypothyroidism caused by destruction of the region by a space-occupying mass is grave.

#### HYPOTHYROIDISM IN CATS

#### Etiology

Iatrogenic hypothyroidism is the most common cause of hypothyroidism in cats and can result from bilateral thyroidectomy, radioactive iodine treatment, or an overdose of antithyroid drugs. Naturally acquired adult-onset primary hypothyroidism is rare. Congenital primary hypothyroidism causing disproportionate dwarfism is recognized more frequently in cats than adult-onset hypothyroidism. Reported causes of congenital hypothyroidism include a defect in thyroid hormone biosynthesis, most notably an iodine organification defect, and thyroid dysgenesis. Goiter is common in cats with defects in thyroid hormone biosynthesis because the hypothalamic-pituitary-thyroid gland axis remains intact. A suspected autosomal recessive inherited defect in iodine organification was documented in a family of Abyssinian cats with congenital hypothyroidism. Although rare, iodine deficiency may cause hypothyroidism in kittens fed a strict all-meat diet.

#### Clinical Signs

Clinical signs of feline hypothyroidism are listed in Box 51-7. The most common are lethargy, inappetence, obesity, and seborrhea sicca. Lethargy and inappetence may become severe. Additional dermatologic signs may include a dry, lusterless, unkempt haircoat; easily epilated hair; poor regrowth

Short limbs

Lethargy

Mental dullness

Constipation

Hypothermia

Bradycardia

Retention of kitten haircoat

Retention of deciduous teeth

of hair; and alopecia. Bradycardia and mild hypothermia may be additional findings on physical examination.

The clinical signs of congenital hypothyroidism are similar to those in dogs (see p. 729). Affected kittens typically appear normal at birth, but delayed growth usually becomes evident by 8 weeks of age. Disproportionate dwarfism develops over the ensuing months, with large heads; short, broad necks; and short limbs developing in affected kittens (Fig. 51-12). Additional findings include lethargy, mental dullness, constipation, hypothermia, bradycardia, and prolonged retention of deciduous teeth. The haircoat may consist mainly of an undercoat with primary guard hairs scattered thinly throughout.

#### Diagnosis

Establishing a diagnosis of hypothyroidism in the cat should be based on a combination of history, clinical signs, physical examination findings, results of routine blood and urine tests, and baseline serum  $T_4$  and  $fT_4$  concentrations. Measurement of serum TSH concentration using the canine TSH

#### FIG 51-12

A 1-year-old domestic long-haired cat with pituitary dwarfism. A comparably aged cat is also present to illustrate the small size of the pituitary dwarf. Note the square, chunky contour of the head and the dull facial expression of the cat—findings that are suggestive of cretinism (see Fig. 49-10, for comparison). The cat had concurrent growth hormone and thyroid hormone deficiency. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

assay should also be considered. Abnormalities identified on routine blood and urine tests include hypercholesterolemia and a mild nonregenerative anemia. Serum T<sub>4</sub> concentration is often used as the initial screening test of thyroid gland function. A normal serum T<sub>4</sub> concentration indicates that the cat is euthyroid. A low serum T<sub>4</sub> concentration in a cat that has undergone thyroidectomy or radioactive iodine treatment or in a kitten with disproportionate dwarfism supports the diagnosis of hypothyroidism. The effect of age should be considered when interpreting serum T<sub>4</sub> concentrations in kittens (see Table 51-2). Because naturally acquired primary hypothyroidism is rare and low serum T4 concentrations in adult cats is almost always caused by nonthyroidal illness (see Fig. 51-13) or some other nonthyroidal factor, the diagnosis of hypothyroidism should never be made solely on the basis of the serum T<sub>4</sub> concentration in an adult cat that has not been previously treated for hyperthyroidism. Documenting a low serum fT4 and high serum TSH concentration and failure of serum T<sub>4</sub> to increase following administration of rhTSH adds further evidence for the diagnosis of hypothyroidism. The definitive diagnosis relies on the cat's response to trial therapy with levothyroxine.

#### **Treatment**

Treatment of hypothyroidism in cats is similar to that used in dogs, which is described in detail on p. 741. Treatment with levothyroxine is indicated for cats with congenital and naturally acquired adult-onset hypothyroidism and for cats with iatrogenic hypothyroidism following treatment for hyperthyroidism that are symptomatic for the disease.

Asymptomatic cats with a low serum T<sub>4</sub> concentration following treatment for hyperthyroidism should not be treated until clinical signs become evident in the hope that additional time will allow atrophied or ectopic thyroid tissue to become functional.

Synthetic levothyroxine is recommended at an initial dosage of 0.05 or 0.1 mg once or twice daily. A minimum of 4 weeks should elapse before the cat's clinical response to treatment is critically assessed. Subsequent evaluations should include a history, physical examination, and measurement of serum T<sub>4</sub> concentration (see the discussion of therapeutic monitoring, p. 742). The goal of therapy is to eliminate the clinical signs of hypothyroidism and prevent signs of hyperthyroidism. This can usually be accomplished by maintaining the serum T<sub>4</sub> concentration between 1.0 and 2.5 µg/dl. The dose and frequency of levothyroxine administration should be adjusted accordingly to attain these goals. If the serum T<sub>4</sub> concentration is within the reference range after 4 to 8 weeks of treatment but there is minimal or no clinical response, the clinician should reassess the diagnosis.

#### **Prognosis**

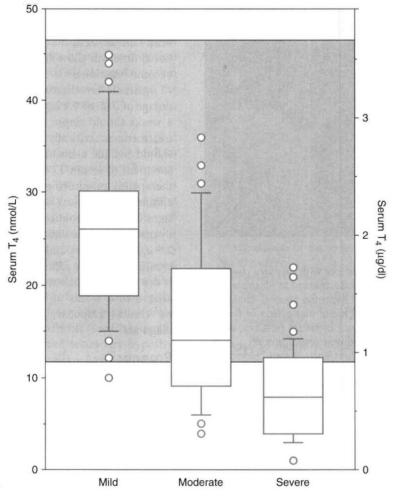

The prognosis for adult cats with hypothyroidism that are receiving appropriate therapy is excellent. The prognosis for kittens with congenital hypothyroidism is guarded and depends on the severity of the skeletal changes at the time treatment is initiated. Although many of the clinical signs resolve with therapy, musculoskeletal problems may persist or develop owing to abnormal bone and joint development.

#### HYPERTHYROIDISM IN CATS

#### Etiology

Hyperthyroidism is a multisystemic disorder resulting from the excessive production and secretion of  $T_4$  and  $T_3$  by the thyroid gland and is almost always a result of chronic intrinsic disease in one or both thyroid lobes. One or more usually small, discrete thyroid masses are palpable in the ventral region of the neck in most cats with hyperthyroidism. Multinodular adenomatous hyperplasia is the most common histologic finding. Less common are thyroid adenomas that cause the lobes to be enlarged and distorted; thyroid carcinoma accounts for fewer than 5% of clinical cases.

One or both thyroid lobes can be affected in thyrotoxic cats. Approximately 20% of hyperthyroid cats have involvement of a single thyroid lobe (Fig. 51-14). The nondiseased thyroid lobe is nonfunctioning and atrophied because of the suppressive effects of the hyperactive thyroid tissue on TSH secretion. More than 70% of hyperthyroid cats have involvement of both thyroid lobes (Fig. 51-15). Of these cats the thyroid lobes are symmetrically enlarged in 10% to 15% and asymmetrically enlarged in the remainder. Approximately 3% to 5% of thyrotoxic cats have hyperactive thyroid

**FIG 51-13**Box plots of serum total T<sub>4</sub> **(A)** and free T<sub>4</sub> **(B)** concentrations in 221 cats with nonthyroidal disease, grouped according to severity of illness. Of 221 cats with nonthyroidal illness 65 had mild disease, 83 had moderate disease, and 73 had severe disease. See Fig. 51-9 for explanation. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal disease, *J Am Vet Med Assoc* 218:529, 2001.)

tissue in the anterior mediastinum, with or without a palpable mass in the neck (Fig. 51-16). Presumably, this tissue represents ectopic thyroid tissue. Functional thyroid carcinoma is the most likely diagnosis if more than two thyroid masses are present (see Fig. 51-16). Some of these cats initially have only one or two thyroid masses, emphasizing the importance of histologic evaluation of surgically removed tissue.

The pathogenesis of adenomatous hyperplastic changes of the thyroid gland remains unclear. It has been postulated that immunologic, infectious, nutritional, environmental, or genetic factors may interact to cause pathologic changes. Epidemiologic studies have identified consumption of commercial canned cat foods as a risk factor for development of hyperthyroidism, suggesting that a goitrogenic compound may be present in the diet. Excessive or deficient iodine

content, isoflavones from soybeans, and chemicals lining pop-top canned foods (specifically bisphenol A) that have migrated into the food during storage have been proposed as potential dietary and chemical goitrogens. Epidemiologic studies suggest that environmental factors such as use of kitty litter may be involved. Recent studies have identified overexpression of the c-ras oncogene in areas of nodular follicular hyperplasia in feline thyroid glands, suggesting that mutations in this oncogene may play a role in the etiopathogenesis of hyperthyroidism in cats (Merryman et al., 1999). In the normal cell activation of the ras protein leads to mitosis. Mutations of the ras oncogene produce mutated ras proteins that are not subject to the normal cellular feedback mechanisms that prevent uncontrolled mitosis. Altered expression of G proteins involved in the signal transduction pathway that stimulates growth and differentiation of thyroid

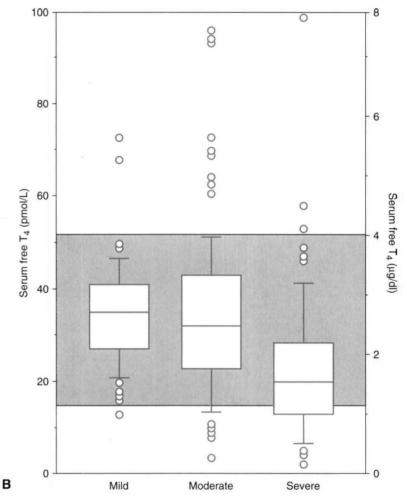

FIG 51-13, cont'd

cells has also been identified in adenomatous thyroid glands obtained from hyperthyroid cats (Ward et al., 2005). Decreased inhibitory G protein expression has been identified, a decrease that creates a relative increase in stimulatory G protein expression that may stimulate unregulated mitogenesis and thyroid hormone production in hyperthyroid cells. Further studies are necessary to clarify the significance of these findings and the relationships among abnormalities identified in thyroid cells from hyperthyroid cats, potential dietary or chemical goitrogens identified in canned cat foods, and the development of hyperthyroidism in cats.

#### **Clinical Features**

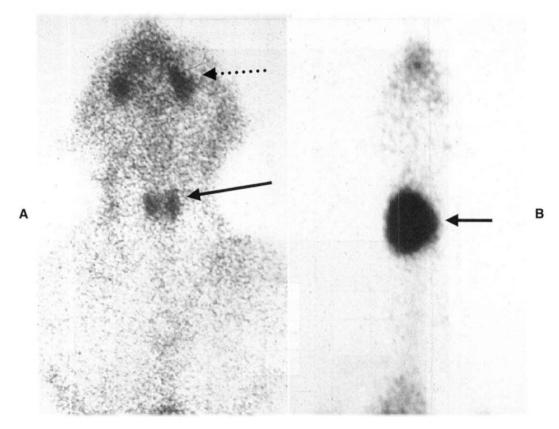

#### **SIGNALMENT**

Hyperthyroidism is the most common endocrine disease affecting cats older than 8 years. The average age at the time of initial presentation to the veterinarian is 13 years, with a range of 4 to 20 years. Fewer than 5% of cats with this disorder are younger than 8 years. There is no sex-related predisposition; domestic short-haired and long-haired cats are

the most frequently affected breeds. Siamese and Himalayans have a decreased risk for development of hyperthyroidism.

#### **CLINICAL SIGNS**

Clinical signs are a result of excessive secretion of thyroid hormone by the thyroid mass. Rarely, a client will seek veterinary care because of an observed mass in the ventrocervical region of the neck. The classic clinical signs of hyperthyroidism are weight loss (which may progress to cachexia), polyphagia, and restlessness or hyperactivity. Additional clinical signs include haircoat changes (patchy alopecia, matted hair, minimal or excessive grooming behavior), polyuria, polydipsia, vomiting, and diarrhea (Table 51-5). Some cats show aggressive behavior that resolves in response to successful treatment of the hyperthyroid state. In some cats lethargy, weakness, and anorexia are the dominant clinical features, in addition to weight loss. Because of the multisystemic effects of hyperthyroidism, the variable clinical signs, and its resemblance to many other diseases of the cat, hyperthyroidism should be suspected in any aged cat with medical problems.

#### FIG 51-14

**A,** Sodium pertechnetate scan of the head, neck, and proximal thorax of a healthy cat. Note that the uptake of pertechnetate (i.e., darkness) is comparable between the two thyroid lobes (solid arrow) and the salivary glands (broken arrow). **B,** Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by unilateral disease affecting the right thyroid lobe (arrow). Note the difference in uptake of pertechnetate between the hyperfunctioning thyroid lobe and the salivary glands.

**TABLE 51-5** 

Clinical Signs and Physical Examination Findings in Cats with Hyperthyroidism

CLINICAL SIGNS	PHYSICAL EXAMINATION FINDINGS	
Weight loss*	Palpable thyroid*	
Polyphagia*	Thin*	
Unkempt haircoat, patchy alopecia*	Hyperactive, difficult to examine*	
Polyuria-polydipsia*	Tachycardia*	
Vomiting*	Hair loss, unkempt hair coat*	
Nervous, hyperactive	Small kidneys	
Diarrhea, bulky stools	Heart murmur	
Decreased appetite	Easily stressed	
Tremor	Dehydrated, cachectic appearance	
Weakness	Premature beats	
Dyspnea, panting	Gallop rhythm	
Decreased activity, lethargy	Aggressive	
Anorexia	Depressed, weak Ventral flexion of the neck	

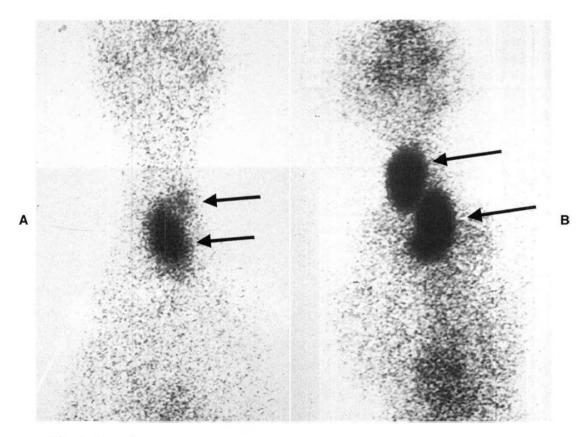

<sup>\*</sup> Common.

#### PHYSICAL EXAMINATION

Physical examination findings are listed in Table 51-5. A discrete thyroid mass is palpable in approximately 90% of cats with hyperthyroidism. However, the palpation of a cervical mass is not pathognomonic for hyperthyroidism. Some cats with palpable thyroid lobes are clinically normal, and some palpable cervical masses are not thyroid in origin. It is frequently difficult to accurately assess unilateral versus bilateral thyroid lobe involvement on the basis of palpation. Two distinct masses cannot always be appreciated on palpation, even if both lobes are large. Large thyroid masses may gravitate to the region of the thoracic inlet, which can interfere with their palpation. The thyroid mass may even descend into the anterior mediastinum. This should be suspected when a thyroid mass is not palpable in a hyperthyroid cat, although a small, nonpalpable mass is also possible.

#### **Clinical Pathology**

Results of a CBC are usually normal. The most common abnormalities are a mild increase in the PCV and mean corpuscular volume. Neutrophilia, lymphopenia, eosinopenia, or monocytopenia is identifed in less than 20% of hyperthyroid cats. Common serum biochemical abnormalities

# A, Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by bilateral, asymmetric disease affecting both thyroid lobes (arrows), with the right lobe more severely involved. This is the most common form of the disease. B, Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by bilateral, symmetric disease affecting both thyroid lobes (arrows). Hypocalcemia after bilateral thyroidectomy is a major concern.

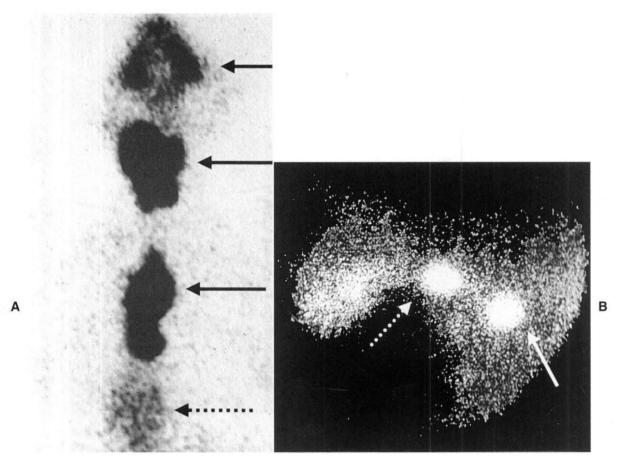

include an increase in serum activities of alanine aminotransferase, alkaline phosphatase, and aspartate aminotransferase; the increase is typically in the mild to moderate range (i.e., 100 to 400 IU/L). One or more of these liver enzymes are increased in approximately 90% of hyperthyroid cats. Additional evaluation of the liver should be considered if liver enzyme activities are greater than 500 IU/L. Increased serum urea nitrogen and creatinine concentrations are identified in approximately 25%, and hyperphosphatemia in 20%, of hyperthyroid cats at our clinic—findings that have important implications regarding treatment (see the discussion of renal insufficiency). Urine specific gravity ranges from 1.008 to greater than 1.050. Most hyperthyroid cats have urine specific gravities greater than 1.035. The remainder of the urinalysis is usually unremarkable unless concurrent diabetes mellitus or urinary tract infection exists.

# COMMON CONCURRENT PROBLEMS Thyrotoxic Cardiomyopathy

Hypertrophic and, less commonly, dilative thyrotoxic cardiomyopathy may develop in cats with hyperthyroidism. Cardiovascular abnormalities detectable during physical examination include tachycardia; a pounding heartbeat noted on palpation of the ventral thorax; and, less frequently, pulse deficits, gallop rhythms, cardiac murmur, and muffled heart sounds resulting from a pleural effusion. Electrocardiographic abnormalities include tachycardia; an increased Rwave amplitude in lead II; and, less commonly, a right bundle-branch block, a left anterior fascicular block, widened QRS complexes, and atrial and ventricular arrhythmias. Thoracic radiographs may reveal cardiomegaly, pulmonary edema, or a pleural effusion. Echocardiographic abnormalities identified in cats with hypertrophic thyrotoxic cardiomyopathy include left ventricular hypertrophy, thickening of the interventricular septum, left atrial and ventricular dilation, and myocardial hypercontractility. Those seen in cats with dilative thyrotoxic cardiomyopathy include subnormal myocardial contractility and marked ventricular dilation. Either form of cardiomyopathy may result in the development of congestive heart failure. Hypertrophic thyrotoxic cardiomyopathy is usually reversible once the hyperthyroid state is corrected, whereas dilative thyrotoxic cardiomyopathy is not.

#### Renal Insufficiency

Hyperthyroidism and renal insufficiency are common diseases of older cats and often occur concurrently. Identification

#### FIG 51-16

Heart (broken arrow). **B,** Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by two hyperfunctioning masses: one located in the neck (broken arrow) and one in the anterior mediastinum (i.e., ectopic site) (solid arrow). Heart (broken arrow).

131 therapy is the treatment of choice for both forms of hyperthyroidism illustrated in this figure.

of small kidneys on physical examination, increased serum urea nitrogen and creatinine concentrations, and urine specific gravity between 1.008 and 1.020 should raise suspicion for concurrent renal insufficiency in a cat with hyperthyroidism. Unfortunately, hyperthyroidism increases glomerular filtration rate (GFR), renal blood flow, and renal tubular resorptive and secretory capabilities in normal and compromised kidneys. Renal perfusion and GFR may acutely decrease and azotemia or clinical signs of renal insufficiency become apparent or significantly worsen after treatment of the hyperthyroid state. It is not easy to determine what impact the hyperthyroid state is having on renal function in cats. The clinical and biochemical manifestations of renal failure may be masked in cats with both thyroid and renal disease in which renal perfusion is enhanced by the circulatory dynamics produced by hyperthyroidism. Thomas Graves, at the University of Illinois, has recently described a group of hyperthyroid cats with urine specific gravities greater than 1.040 that developed renal failure after treatment for hyperthyroidism, suggesting that urine specific gravity is a poor predictor of renal function in cats with hyperthyroidism. For these reasons cats with hyperthyroidism should initially be given reversible therapy (i.e., oral antithyroid drugs) until the impact of establishing euthyroidism on renal function can be determined (see p. 749).

#### **Urinary Tract Infections**

Urinary tract infections are relatively common in untreated hyperthyroid cats, with a reported prevalence of 12% to 22%. The most common bacterial isolate is *Escherichia coli*. Urine culture is indicated in hyperthyroid cats with lower urinary tract signs or presence of bacteriuria, pyuria, or both on urinalysis. Unfortunately, most hyperthyroid cats are asymptomatic for urinary tract infection, suggesting that urine culture should be a routine part of the complete diagnostic evaluation of cats with newly diagnosed hyperthyroidism.

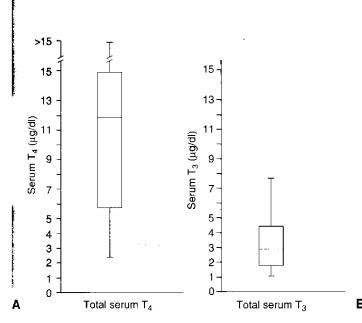

FIG 51-17

Mean and range of random total serum  $T_4$  (A) and total serum  $T_3$  (B) concentrations in hyperthyroid cats. Seventy-five percent of hyperthyroid cats have values within the box, and the balance is within the limitation bars above and below the box. Note that virtually all hyperthyroid cats have abnormal or borderline serum  $T_4$  concentrations, whereas serum  $T_3$  concentrations are less sensitive. The pink region represents the normal reference range.

#### **Systemic Hypertension**

Systemic hypertension is common in cats with hyperthyroidism and results from the effects of increased  $\beta$ -adrenergic activity on heart rate, myocardial contractility, systemic vasodilation, and activation of the renin-angiotensin-aldosterone system. Hypertension caused by hyperthyroidism is usually clinically silent. Retinal hemorrhages and retinal detachment are the most common clinical complications of systemic hypertension in hyperthyroid cats, but in general, ocular lesions are not commonly identified.

#### **Gastrointestinal Tract Disorders**

Gastrointestinal tract signs are common in cats with hyperthyroidism and include polyphagia, weight loss, anorexia, vomiting, diarrhea, increased frequency of defecation, and increased volume of feces. Intestinal hypermotility and malassimilation have been documented in some cats with hyperthyroidism and are responsible for producing some of the gastrointestinal tract signs. Inflammatory bowel disease is a common concurrent gastrointestinal tract disorder that should be considered in any hyperthyroid cat that has persistence of gastrointestinal signs after correction of the hyperthyroid state (see Chapter 33). Intestinal neoplasia, most notably lymphoma, is perhaps the most important differential diagnosis in cats seen because of polyphagia and weight loss. The abdomen should be carefully palpated in a search for thickening of the intestinal tract and mesenteric lymphadenopathy—findings that may be the only clues for

TABLE 51-6

Interpretation of Baseline Serum Thyroxine (T<sub>4</sub>)
Concentration in Cats with Suspected Hyperthyroidism

SERUM T4 CONCENTRATION	PROBABILITY OF HYPERTHYROIDISM	
>5.0 µg/dl	Very likely	
3.0-5.0 µg/dl	Possible	
2.5-3.0 µg/dl	Unknown	
2.0-2.5 µg/dl	Unlikely	
<2.0 µg/dl	Very unlikely*	

<sup>\*</sup> Assuming that a severe systemic illness is not present.

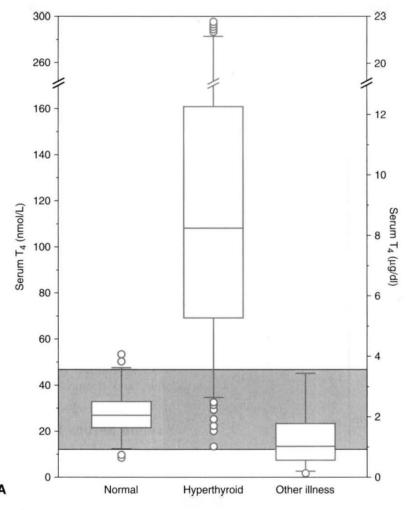

intestinal lymphoma. Abdominal ultrasonography may also provide clues to the possibility of lymphoma.

#### Diagnosis

The diagnosis of hyperthyroidism is based on identification of appropriate clinical signs, palpation of a thyroid nodule, and documentation of an increased serum  $T_4$  concentration.

#### Baseline Serum T<sub>4</sub> Concentration

Measurement of random baseline serum T<sub>4</sub> concentration has been extremely reliable in differentiating hyperthyroid cats from those without thyroid disease (Fig. 51-17). An abnormally high scrum T<sub>4</sub> concentration strongly supports the diagnosis of hyperthyroidism, especially if appropriate clinical signs are present, and a low serum T<sub>4</sub> concentration rules out hyperthyroidism, except in extremely uncommon situations when severe life-threatening nonthyroidal illness is present (Table 51-6). Serum T<sub>4</sub> concentrations that fall within the upper half of the normal range (i.e., 2.5 to 5.0 µg/ dl) create a diagnostic dilemma, especially if clinical signs are suggestive of hyperthyroidism and a nodule is palpable in the ventral region of the neck. This combination of findings is referred to as occult hyperthyroidism and is most commonly identified in cats in the early stages of hyperthyroidism. Serum T<sub>4</sub> concentrations are more likely to be influenced by nonthyroidal factors such as concurrent illness and are more likely to randomly fluctuate into the reference range in cats with mild hyperthyroidism, compared with cats with more advanced disease (Fig. 51-18; see also Fig. 51-13). The diagnosis of hyperthyroidism should not be excluded on the basis of one "normal" serum T<sub>4</sub> test result, especially in a cat with appropriate, albeit often mild, clinical signs and a palpable mass in the neck. Additional diagnostic factors to consider include measurement of serum free T<sub>4</sub> (fT<sub>4</sub>), the T<sub>3</sub> suppression test, sodium pertechnetate thyroid scan, or repetition of the serum T<sub>4</sub> test 3 to 6 months later. It is important to remember that the thyroid nodule may also be nonfunctional and the clinical signs may be the result of another disease (see Chapter 54).

Box plots of serum total T<sub>4</sub> **(A)** and free T<sub>4</sub> **(B)** concentrations in 172 clinically normal cats, 917 cats with untreated hyperthyroidism, and 221 cats with nonthyroidal disease. See Fig. 51-9 for explanation. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal disease, *J Am Vet Med Assoc* 218:529, 2001.)

#### Serum Free T<sub>4</sub> Concentration

Measurement of serum fT<sub>4</sub> using equilibrium dialysis or the 2-step RIA (see p. 733) is the current recommendation of choice to confirm hyperthyroidism in a cat with nondiagnostic serum T<sub>4</sub> test results. Measurement of serum fT<sub>4</sub> is a more reliable means of assessing thyroid gland function than serum T<sub>4</sub> concentration, in part because nonthyroidal illness has less of a suppressive effect on serum fT<sub>4</sub> than T<sub>4</sub> (see Fig. 51-13) and serum  $fT_4$  is increased in many cats with occult hyperthyroidism and "normal" T4 test results. Because of cost, measurement of serum fT4 is often reserved for cats with suspected hyperthyroidism in which T<sub>4</sub> values are nondiagnostic. Concurrent illness may increase the serum fT4 concentration in cats, an increase that can exceed the reference range (see Fig. 51-18). For this reason serum fT4 concentration should always be interpreted in conjunction with a T<sub>4</sub> concentration measured from the same blood sample. An increased serum fT<sub>4</sub> concentration in conjunction with

high-normal or increased serum  $T_4$  concentration is supportive of hyperthyroidism. An increased serum  $fT_4$  concentration in conjunction with a low-normal or low serum  $T_4$  concentration is supportive of the euthyroid sick syndrome rather than hyperthyroidism.

#### T<sub>3</sub> Suppression Test

The  $T_3$  suppression test is used to distinguish euthyroid from mildly hyperthyroid cats in cases in which  $T_4$  and  $fT_4$  test results are nebulous. The  $T_3$  suppression test is based on the theory that oral administration of  $T_3$  will suppress pituitary TSH secretion in euthyroid cats, resulting in a decrease in circulating  $T_4$  (Fig. 51-19). In contrast, pituitary TSH secretion is already suppressed in cats with hyperthyroidism, oral administration of  $T_3$  will not cause further suppression, and serum  $T_4$  will not decrease following  $T_3$  administration. In this test 25  $\mu$ g of  $T_3$  (e.g., Cytomel, King Pharmaceuticals) is administered orally three times per day for seven treat-

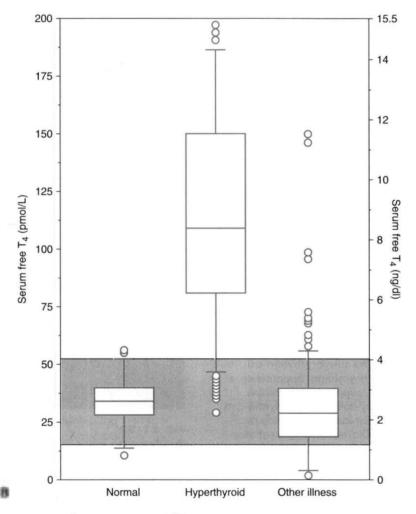

FIG 51-18, cont'd

ments and serum T<sub>4</sub> and T<sub>3</sub> concentration is determined before and 8 hours after the last T<sub>3</sub> administration. Normal cats consistently have postdosing serum T<sub>4</sub> concentrations of less than 1.5 ug/dl, whereas hyperthyroid cats have postdosing T<sub>4</sub> concentrations of greater than 2.0 µg/dl. Values of 1.5 to 2.0 µg/dl are nondiagnostic. The percentage decrease in the serum T<sub>4</sub> concentration is not as reliable a gauge as the absolute value, although suppression of more than 50% below the baseline value occurs in normal but not hyperthyroid cats. Serum T<sub>3</sub> concentrations are used to determine whether the client has successfully administered the thyroid medication to the cat. Serum T<sub>3</sub> concentration measured in the postpill blood sample should be increased compared with results obtained before initiating the test in all cats properly tested, regardless of the status of thyroid gland function.

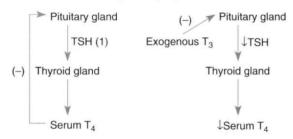

#### Radionuclide Thyroid Scanning

Radionuclide thyroid scanning identifies functional thyroid tissue and is used as a diagnostic test in cats with suspected occult hyperthyroidism; to identify ectopic thyroid tissue in cats with appropriate signs of hyperthyroidism and increased serum T<sub>4</sub> concentrations but no palpable thyroid

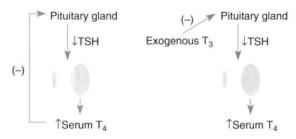

nodule in the neck; to identify sites of metastasis in cats with thyroid carcinoma; and to provide guidance for developing the best treatment plan, especially if thyroidectomy is being considered. Radioactive technetium 99m (pertechnetate) is used for routine imaging of the thyroid gland in cats. It has a short physical half-life (6 hours), is concentrated within functioning thyroid follicular cells, and reflects the trapping mechanism of the gland. Because antithyroid drugs do not affect the trapping mechanism of the thyroid pump, a pertechnetate scan can be done in cats being treated with antithyroid drugs. Salivary glands and the gastric mucosa also concentrate pertechnetate; it is excreted by the kidneys.

Scanning of the thyroid provides a picture of all functioning thyroid tissue and permits the delineation and localization of functioning as opposed to nonfunctioning areas of the thyroid. Fig. 51-14 shows the similarity between the size and shape of the thyroid lobes and similarity of radionuclide uptake by the thyroid and salivary glands in a normal cat. This 1:1 ratio of salivary gland to thyroid lobe uptake is the standard by which to judge the status of the thyroid. Findings in most hyperthyroid cats are markedly abnormal and usually easy to interpret (see Figs. 51-14 to 51-16).

#### Normal pituitary-thyroid axis

#### Hyperthyroidism

#### FIG 51-19

Effect of  $T_3$  supplementation on the pituitary-thyroid axis in healthy cats and cats with hyperthyroidism. Suppression of pituitary TSH secretion by the  $T_3$  supplement decreases serum  $T_4$  concentration in healthy cats. In hyperthyroid cats the serum TSH concentration is already suppressed; the  $T_3$  supplementation has no effect. The serum  $T_4$  concentration remains increased.

#### **Cervical Ultrasound**

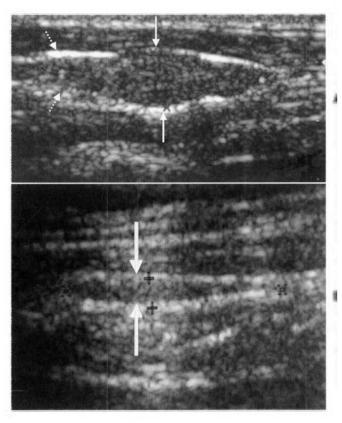

Ultrasonographic evaluation of the thyroid gland can be used to confirm the origin of the palpable cervical mass, differentiate unilateral versus bilateral thyroid lobe involvement, assess the size of the thyroid mass(es), and provide guidance for developing the best treatment plan (Fig. 51-20). Ultrasound does not provide information on the functional status of the thyroid mass and should not be used for establishing the diagnosis of hyperthyroidism. Rather, cervical ultrasound should be used as an adjunctive tool for locating cervical thyroid tissue.

#### **Treatment**

Hyperthyroidism in cats can be managed by thyroidectomy, oral antithyroid medications, or radioactive iodine (Table 51-7). All three modes of therapy are effective. Surgery and radioactive iodine treatments are used in the hope of providing a permanent cure for the disease; oral antithyroid drugs only control the hyperthyroidism and must be given daily to achieve and maintain their effect.

#### **Initial Treatment Recommendation**

Hyperthyroid cats should be treated initially with an oral antithyroid drug (i.e., methimazole) to reverse the hyperthyroid-induced metabolic and cardiac derangements, decrease the anesthetic risk associated with thyroidectomy, and assess the impact of treatment on renal function. Hyperthyroidism

#### FIG 51-20

Normal appearing portion of thyroid lobe (broken arrows). **B,** Ultrasound image of the small (atrophied) normal left thyroid lobe (solid arrows). Left thyroid lobe (small arrows). Results of the ultrasound examination supported unilateral disease affecting the right thyroid lobe, which was confirmed with a sodium pertechnetate scan.

may mask renal insufficiency in some cats (see p. 749), and azotemia may develop or worsen and clinical signs of renal insufficiency may develop after treatment of the hyperthyroid state. Because it is not easy to determine what impact the hyperthyroid state is having on renal function, it is preferable to treat cats with reversible therapy (i.e., methimazole) until the impact of hyperthyroidism on renal function can be determined. If renal parameters remain static or improve after resolution of hyperthyroidism with methimazole, a more permanent treatment can be recommended. If significant azotemia or clinical signs of renal insufficiency develop during methimazole therapy, the treatment protocol for methimazole should be modified to attain the best possible control of both disorders and treatment for renal insufficiency should be instituted. Maintaining a mild hyperthyroid state may be necessary to improve renal perfusion and GFR and prevent the uremia of renal failure.

#### **Antithyroid Drugs**

Oral antithyroid drugs include methimazole, propylthiouracil, and carbimazole. Oral antithyroid drugs are inexpensive,

TABLE 51-7

Indications, Contraindications, and Disadvantages of the Three Modes of Therapy for Hyperthyroidism in Cats

THERAPY	INDICATIONS	RELATIVE CONTRAINDICATIONS	DISADVANTAGES
Methimazole, propylthiouracil, carbimazole	Long-term therapy for all forms of hyperthyroidism; initial therapy to stabilize cat's condition and assess renal function before thyroidectomy or radioactive iodine	None	Daily therapy required; no effect on growth of thyroid; mild adverse reactions common; severe reactions possible
Thyroidectomy	Unilateral lobe involvement; bilateral lobe involvement, asymmetrical sizes	Ectopic thyroid lobe; metastatic carcinoma; bilateral, symmetric, large lobes (high risk of hypocalcemia); severe systemic signs; cardiac arrhythmias or failure; renal insufficiency	Anesthetic risks; relapse of disease; postoperative complications, especially hypocalcemia
Radioactive iodine (131)	Therapy for all forms of hyperthyroidism; treatment of choice for ectopic thyroid lobe and thyroid carcinoma	Renal insufficiency	Limited availability; hospitalization time; potential for retreatment; hazardous to humans

readily available, relatively safe, and effective in the treatment of hyperthyroidism in cats. They inhibit the synthesis of thyroid hormone by blocking the incorporation of iodine into the tyrosyl groups in thyroglobulin and by preventing the coupling of these iodotyrosyl groups into T<sub>3</sub> and T<sub>4</sub>. Antithyroid drugs do not block the release of stored thyroid hormone into the circulation and do not have antitumor actions. Oral antithyroid drugs do not interfere with results of pertechnetate scanning or radioactive iodine therapy. Indications for oral antithyroid drugs include (1) test treatment to normalize serum T<sub>4</sub> concentrations and assess the effect of resolving hyperthyroidism on renal function, (2) initial treatment to alleviate or eliminate any medical problems associated with the syndrome before thyroidectomy is performed or before the hospitalization required for radioactive iodine treatment, and (3) long-term treatment of hyperthyroidism.

Methimazole (Tapazole; Eli Lilly & Co.) is currently the antithyroid drug of choice because the incidence of adverse reactions associated with its use is lower than that associated with the use of propylthiouracil (Table 51-8). Adverse reactions are less likely to occur when the dosage of methimazole is started low (typically at subtherapeutic dose initially) and gradually increased to effect. The recommended initial dose of methimazole is 2.5 mg administered orally twice a day for 2 weeks. If adverse reactions are not observed by the client, if the physical examination reveals no new problems, if results of a CBC and platelet count are within reference limits, if the serum creatinine and urea nitrogen concentrations have not increased, and if serum T4 concentration is greater than 2 µg/dl after 2 weeks of therapy, the dose is increased by 2.5 mg per day (i.e., 5 mg in the morning and 2.5 mg in the evening) twice daily and the same parameters evaluated 2 weeks later. The dosage should continue to be increased every 2 weeks by 2.5 mg/day increments until the serum  $T_4$  concentration is between 1 and 2  $\mu$ g/dl or adverse reactions develop. Serum  $T_4$  concentrations decline into the reference range within 2 weeks once the cat is receiving an effective dose of methimazole; clinical improvement is usually noted by clients within 2 to 4 weeks once good control of serum  $T_4$  concentration is achieved. Most cats respond to 5 to 7.5 mg of methimazole per day, and the drug is most effective when given twice a day. Attempts at decreasing the daily dosage, frequency of administration, or both can take place once clinical signs have resolved and a euthyroid state is attained, especially for cats receiving chronic methimazole treatment.

Rarely, cats are encountered that seem particularly resistant to methimazole, requiring as much as 20 mg/day. The most common cause for apparent resistance to methimazole is the inability of some clients to administer the drug to their cats. One alternative is to have a compounding pharmacy incorporate methimazole into tasty kitty treats. Another alternative is the topical application of methimazole to the pinna of the ear. Compounding veterinary pharmacies offer transdermal methimazole in a pluronic lecithin organogel (PLO) formulation. Creams can be made with methimazole at any concentration and are usually provided in 1-cc syringes that allow the client to place the appropriate dose on the fingertip and rub the cream into the pinna of the cat's ear. The client must wear gloves to avoid absorption of methimazole, should alternate ears, and should wipe away any residual cream 30 to 60 minutes after each administration. The dosage and frequency of administration is as discussed with oral methimazole treatment. The bioavailability of transdermal methimazole is more variable, the overall effectiveness

is not as good, and the prevalence of gastrointestinal adverse effects is lower, compared with oral methimazole. One important concern with using transdermal methimazole is the lack of regulation of compounding pharmacies; consistency between products created can vary considerably.

Adverse reactions to methimazole typically occur within the first 4 to 8 weeks of therapy (see Table 51-8). The cat should be examined every 2 weeks during the initial 3 months of methimazole treatment and a CBC, platelet count, assessment of kidney function, and serum T<sub>4</sub> concentration evaluated at each visit. After the initial 3 months of therapy a CBC, platelet count, serum biochemistry panel, and serum T<sub>4</sub> concentration should be evaluated every 3 to 6 months. Using the dosing protocol described above, lethargy, vomiting, and anorexia occur in fewer than 10% of cats; these mild adverse reactions are usually transient and often resolve despite continued administration of the drug. Mild methimazoleinduced hematologic changes occur in fewer than 10% of cats and include eosinophilia, lymphocytosis, and transient leukopenia. More worrisome but less common (fewer than 5% of cats) alterations include facial excoriations, thrombocytopenia (platelet counts less than 75,000/mm³), leukopenia (total white blood cell counts less than 2000/mm<sup>3</sup>), and immune-mediated hemolytic anemia. Apparent hepatic toxicity or injury occurs in fewer than 2% of cats receiving methimazole and is characterized by clinical signs of liver disease (i.e., lethargy, anorexia, vomiting), icterus, and increased serum alanine transaminase and alkaline phosphatase activities. Some cats test positive for antinuclear antibodies, but the importance of this finding is not known. Development of myasthenia gravis has also been reported with methimazole treatment. If any of these serious complications develop, methimazole treatment should be discontinued and supportive care given. Adverse reactions typically resolve within 1 week after methimazole treatment is discontinued. It is common for these potentially life-threatening adverse reactions to recur, regardless of the dose or type of antithyroid drug used; thus alternative therapy (i.e., surgery, radioactive iodine) is recommended.

Carbimazole (NeoMercazole; Amdipharm) is an antithyroid drug that is converted to methimazole in vivo; it is an effective alternative treatment if methimazole is not available. The dosage and frequency of administration are the same as those in oral methimazole treatment. Long-term, twice-daily schedules are effective in controlling hyperthyroidism. Adverse reactions are similar to those seen in cats receiving methimazole, but they occur less frequently. Cats being treated with carbimazole should be monitored in the same manner as that suggested for cats receiving methimazole.

#### Surgery

Thyroidectomy is an effective treatment but should always be considered an elective procedure. Surgery is not indicated if the risk of anesthesia in the cat is unacceptable, its renal function is questionable, the likelihood of postoperative hypocalcemia is great, ectopic thyroid tissue is present in the thorax, or thyroid carcinoma with metastasis is suspected. Treatment with methimazole for 1 to 2 months before thyroidectomy is recommended for reasons previously discussed. If possible, an ultrasound examination of the ventral neck or a radionuclide scan should be performed before surgery to identify the location of the abnormal thyroid tissue, differentiate unilateral from bilateral lobe involve-

No amelioration of the hyperthyroidism

ment, and provide some insight into the probability of hypocalcemia developing postoperatively (see Fig. 51-15). Similar information can also be gained by direct visualization at the time of surgery.

Postoperative complications are listed in Box 51-8. The most worrisome is hypocalcemia. There is a direct correlation between the size of the thyroid lobes, the inability to visualize the external parathyroid glands, and the risk of hypocalcemia. Care must be taken to preserve at least one, preferably both, external parathyroid glands and their associated blood supply. A "subcapsular" thyroidectomy affords the best chance of retaining functional parathyroid glands. (See Suggested Readings for thyroidectomy procedures.) If all four parathyroid glands are inadvertently removed, the two external parathyroid glands should be removed from their respective thyroid lobes, minced, and placed within the muscle belly of one of the sternohyoideus muscles by bluntly dissecting parallel to the muscle fibers. Hypoparathyroidism usually resolves within a month of surgery if revascularization of the parathyroid autotransplant occurs.

Serum calcium concentration should be assessed at least once daily for 5 to 7 days if a bilateral thyroidectomy has been performed. Clinical signs of hypocalcemia typically develop within 72 hours of surgery, although signs may not develop for 7 to 10 days. These signs include lethargy, anorexia, reluctance to move, facial twitching (especially the ears), muscle tremors and cramping, tetany, and convulsions. If all four parathyroid glands are removed at surgery, appropriate calcium and vitamin D supplementation should be initiated once the cat has recovered from anesthesia (see p. 735). If at least one parathyroid gland has been spared, transient hypocalcemia may still develop and last for several days to weeks, probably as a result of disruption of blood flow to the parathyroid gland after surgical manipulation. In these cats oral vitamin D and calcium therapy should be initiated only if clinical signs develop or if hypocalcemia becomes severe (i.e., serum total or ionized calcium concentration less than 8 mg/dl and 0.8 mmol/L, respectively). A decline in the blood calcium concentration is not an absolute indication to begin therapy because the remaining parathyroid glands may respond before clinical signs or severe hypocalcemia develop.

The persistence of hypoparathyroidism is unpredictable. Parathyroid function may recover after days, weeks, or months of vitamin D and calcium supplementation. Whenever resolution of hypoparathyroidism is observed, it is assumed that reversible parathyroid damage occurred, accessory parathyroid tissue may be starting to compensate for glands damaged or removed at surgery, or the parathyroid autotransplant (if performed at surgery) has revascularized and become functional. It is also possible that calcium-regulating mechanisms are functioning in the absence of parathyroid hormone. Because it is difficult to predict the long-term requirement for vitamin D therapy in any cat, an attempt should be made to gradually wean all treated cats off medication while monitoring the serum calcium concentration. The tapering process should extend over a period of at least 12 to 16 weeks. The goal is to maintain the serum calcium concentration between 8.5 and 10.0 mg/dl. If hypocalcemia recurs, therapy with vitamin D and calcium must be reinstituted.

Hypothyroidism may develop in some cats after bilateral thyroidectomy. The clinical signs, diagnosis, and treatment are discussed on p. 744. The decision to initiate levothyroxine treatment should be based on the presence or absence of clinical signs, not on the serum  $T_4$  concentration, per se. Serum  $T_4$  concentrations commonly decrease after surgery, often to less than 0.5  $\mu g/dl$ , but thyroid function returns in most cats before clinical signs become apparent. Thyroid hormone supplementation should be initiated in cats that develop clinical signs in conjunction with a low serum  $T_4$  concentration. Because thyroid replacement therapy may not be needed long term in some of these cats, thyroid replacement therapy should be tapered slowly and then discontinued after 1 to 3 months to determine the continued need for treatment.

If clinical signs of hyperthyroidism persist despite thyroidectomy, the serum T4 concentration should be measured. If the serum T<sub>4</sub> concentration is low-normal or low (i.e., <2.0 µg/dl), another disorder should be suspected. If the serum T<sub>4</sub> concentration is high-normal or high (i.e., >4.0 µg/dl), ectopic abnormal thyroid tissue, metastatic thyroid carcinoma, or, if unilateral thyroidectomy was performed, abnormal tissue in the remaining thyroid lobe should be suspected. Ectopic thyroid tissue would most likely be in the mediastinum, cranial to the heart (see Fig. 51-16). Thyroid scanning is recommended to identify ectopic or metastatic thyroid tissue. Alternatively, oral methimazole or radioactive iodine therapy can be considered. Clinical signs of hyperthyroidism may also recur months to years after thyroidectomy. The serum T4 concentration should be monitored once or twice a year in all cats successfully treated with surgery.

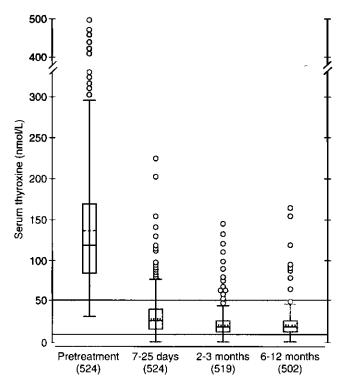

FIG 51-21
Box plots of serum thyroxine (T₄) concentrations in 524 cats before and at various times after administration of radioiodine for treatment of hyperthyroidism. The shaded area indicates the reference range for serum T₄ concentration. Please see Fig. 51-9 for the key. (From Peterson ME et al: Radioiodine treatment of 524 cats with hyperthyroidism, J Am Vet Med Assoc 207:1422, 1995.)

#### Radioactive Iodine

If available, radioactive iodine is the treatment of choice for hyperthyroidism because of the very low morbidity and mortality and very high success rate associated with the treatment (Fig. 51-21). Hypoparathyroidism is not a concern with radioactive iodine treatment, is effective in cats with hyperfunctioning ectopic thyroid tissue, and is the only option offering the potential for a cure in cats with metastatic or nonresectable thyroid carcinoma. Treatment with methimazole for 1 to 2 months before radioactive iodine treatment is recommended for reasons previously discussed. Prior or current treatment with methimazole does not alter the efficacy of radioactive iodine treatment.

Iodine 131 (<sup>131</sup>I) has a half-life of 8 days and is the radionuclide of choice for treating hyperthyroidism. <sup>131</sup>I administered intravenously or subcutaneously is concentrated within the thyroid, and the emitted radiation destroys surrounding functioning follicular cells while causing minimal radiation damage to contiguous structures. At doses of 3 to 5 mCi of <sup>131</sup>I, the thyroid cells killed are those that are functioning. Atrophied normal thyroid cells receive a relatively small dose of radiation and are usually able to return to function, thereby preventing hypothyroidism in most cats. Depending on the dose administered, more than 80% of treated cats become euthyroid within 3 months—most within 1 week and more than 95% of treated cats are euthyroid at 6 months. In one study by Peterson et al. (1995), clinical signs and laboratory data consistent with hypothyroidism developed in approximately 2% of 254 131 I-treated cats, 2% to 4% required a second 131I treatment, and hyperthyroidism recurred in 2% within 1 to 6 years of treatment. Chun et al. (2002) found no correlation between pretreatment serum T<sub>4</sub> concentration or thyroid to salivary gland ratios and resolution of hyperthyroidism after treatment with radioactive iodine. The most common complication following radioactive iodine treatment is hypothyroidism, which typically develops in cats with large, diffusely affected thyroid lobes receiving large doses of <sup>131</sup>I. The duration of hospitalization following 131I administration varies depending on state regulations and the dosage of 131 I administered. In our hospital the average cat is treated with 3 to 5 mCi of <sup>131</sup>I and requires 4 to 6 days of hospitalization after therapy until the radioactivity of the cat and its excretions reach an acceptable level.

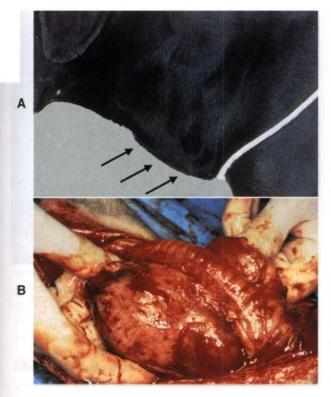

#### **Prognosis**

The prognosis is excellent for most cats with hyperthyroidism, assuming concurrent disease can be managed and thyroid carcinoma is not the etiology. Surgery and <sup>131</sup>I therapy have the potential for cure, although hyperthyroidism may recur months to years (or not at all) after thyroidectomy or <sup>131</sup>I treatment. Hyperthyroid cats with adenomatous hyperplasia or adenoma can potentially be treated with methimazole for years, assuming adverse reactions related to the medication are avoided. In a recent retrospective study cats with concurrent renal disease had significantly shorter survival times than cats with normal renal function and the survival time in cats treated with methimazole alone (median 2 years; interquartile range 1 to 3.9 years) was significantly shorter than cats treated with <sup>134</sup>I alone (4.0 years; 3.0 to 4.8 years) or methimazole followed by <sup>131</sup>I (5.3 years; 2.2 to 6.5 years; Milner et al., 2006).

#### CANINE THYROID NEOPLASIA

#### Etiology

Thyroid adenomas are usually small, nonfunctional masses that do not cause clinical signs and are usually found incidentally at necropsy. Exceptions are thyroid adenomas that are functional and cause hyperthyroidism or are unexpectedly identified during ultrasound examination of the ventral neck. Thyroid carcinomas are more commonly identified antemortem because of their large size, presence of clinical signs that can be recognized by clients, and ease of palpation by veterinarians. One or both thyroid lobes may be involved, and ectopic thyroid tissue located in the anterior mediastinum and base of the heart occasionally may become neoplastic. Thyroid carcinomas frequently infiltrate into surrounding structures such as the esophagus, trachea, and cervical musculature. Regional and distant metastasis to the

#### FIG 51-22

**A,** A 13-year-old male Labrador Retriever was presented to the veterinarian because the client noticed a mass in the neck (arrows). The mass was a thyroid adenocarcinoma. **B,** Thyroid adenocarcinoma in an 11-year-old mixed-breed dog. Clinical signs included dysphagia, coughing, and a visible mass in the ventral region of the neck.

retropharyngeal and cervical lymph nodes and lungs is common. Metastasis to other locations such as the liver, kidney, bone, and brain is also possible.

Most dogs with thyroid tumors are euthyroid or hypothyroid; approximately 10% of dogs have functional thyroid tumors that secrete excess thyroid hormone, causing hyperthyroidism. Clinical signs of hyperthyroidism may predominate in these dogs. Hyperthyroidism may be caused by functional thyroid adenomas and carcinomas. Adenomatous hyperplasia is the most common cause of hyperthyroidism in cats but has not been described in dogs.

#### **Clinical Features**

Thyroid tumors occur in middle-aged to older dogs, with an average age of 10 years. There is no sex-related predilection. Although any breed can be affected, Boxers, Beagles, and Golden Retrievers may be at an increased risk.

Dogs with nonfunctional thyroid tumors are usually brought to veterinarians because the client has seen or felt a mass in the ventral region of the dog's neck (Fig. 51-22). Clinical signs may develop as a result of the mass compressing on adjacent structures (e.g., dyspnea, dysphagia) or as a result of metastasis (e.g., exercise intolerance, weight loss; Box 51-9). Clinical signs of hypothyroidism may develop

#### BOX 51-9

with large invasive tumors that destroy both thyroid lobes. Clinical signs of hyperthyroidism occur in approximately 10% of dogs with thyroid tumors and are similar to those seen in hyperthyroid cats (see p. 748).

Most thyroid tumors are firm, asymmetric, lobulated, and nonpainful masses located close to the typical thyroid region in the neck. The mass is usually well embedded in surrounding tissue and not freely movable. Additional physical examination findings may include dyspnea, cough, cachexia, lethargy, Horner's syndrome, and dehydration. A dry, lusterless haircoat is common, but alopecia is rare. Mandibular or cervical lymph nodes (or both) may be enlarged as a result of tumor spread or lymphatic obstruction. Dogs with functional thyroid tumors may be restless, thin, and panting, and auscultation of the heart frequently reveals tachycardia. Surprisingly, many dogs are found to be remarkably healthy on physical examination.

CBC, serum biochemistry panel, and urinalysis findings usually do not help establish the diagnosis. A mild normocytic, normochromic, nonregenerative anemia, hypercholesterolemia, and hypertriglyceridemia causing lipemia may be present in dogs with concurrent hypothyroidism. A mild increase in the blood urea nitrogen concentration and liver enzyme activities has been identified in less than 35% of dogs; however, the latter changes were not found to be indicative of hepatic metastasis. Hypercalcemia has also been noted in a few dogs.

Baseline serum  $T_4$  and  $fT_4$  concentrations are increased and serum TSH is undetectable in dogs with a functional thyroid tumor causing hyperthyroidism. However, most canine thyroid tumors are nonfunctional, and most of these

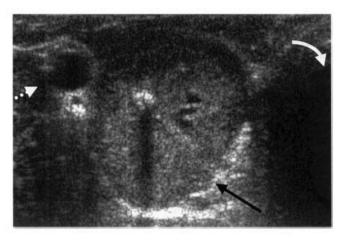

FIG 51-23

Ultrasound image of a mass in the region of the right thyroid lobe (straight arrow), the carotid artery (broken arrow), and the trachea (curved arrow) in an 11-year-old female spayed Labrador mix. A small region of mineralization causing a shadowing effect is evident within the mass. The mass was an unexpected finding during a routine physical examination. Thyroid adenocarcinoma was the histopathologic diagnosis after surgical removal of the mass.

dogs are found to be euthyroid when serum thyroid hormone concentrations are evaluated. Approximately 30% of dogs with thyroid tumors have serum  $T_4$  and  $fT_4$  concentrations below the reference range and suggestive of hypothyroidism resulting from destruction of normal thyroid tissue by the tumor. However, interpretation of low serum thyroid hormone concentrations must be done with caution and consideration of the suppressive effects of nonthyroidal illness on thyroid function (see p. 737).

Cervical ultrasonography will confirm the presence of a mass, regardless of its size and location; can distinguish between cavitary, cystic, and solid tumors; can identify the presence and severity of local tumor invasion; can identify the presence and location of metastatic sites in the cervical region; and improve the likelihood that representative tissue for cytologic or histologic evaluation is obtained during fineneedle aspiration or percutaneous biopsy of the mass (Fig. 51-23). Because metastasis to the lungs and base of the heart is common with thyroid carcinoma, thoracic radiographs should always be included in the diagnostic evaluation of dogs with a suspected thyroid mass. Cervical radiographs may identify a small mass that was suspected but not definitively identified on physical examination, may show the severity of the displacement of adjacent structures, and may identify local invasion of the mass into the larynx and trachea. Abdominal ultrasonography can be used to identify abdominal (most notably hepatic) metastatic lesions. Computed tomographic and magnetic resonance imaging can define the extent of tumor invasion into surrounding structures, identify distant metastasis to the lymph nodes and lung, and identify ectopic thyroid tissue in the mediastinum (Fig. 51-24)—information that is valuable if surgery or megavoltage irradiation is being considered.

FIG 51-24

Magnetic resonance image of a right-sided thyroid mass (solid arrow) adjacent to the trachea (broken arrow) in a 10-year-old male castrated Golden Retriever that was presented for a swelling in the neck. The histopathologic diagnosis was thyroid C-cell carcinoma with vascular invasion. The affected region of the neck was treated with radiation after thyroidectomy.

Thyroid scans using sodium pertechnetate can be used to confirm that a cervical mass is thyroid in origin; assess the degree of regional tissue invasion; and identify unusual areas of uptake in the head, neck, and thorax suggestive of metastatic sites. Most thyroid carcinomas demonstrate heterogenous uptake of pertechnetate, irregular gland shape, and evidence of regional tissue invasion. If the malignancy, especially a distant site of metastasis, does not trap iodine effectively, the scintigraphic study will fail to identify the site. Failure to identify distant metastatic sites with scintigraphy does not mean that distant metastasis does not exist. The amount of radionuclide uptake by the thyroid tumor is not a reliable indicator of its functional status (i.e., euthyroid, hypothyroid, or hyperthyroid) or the benign versus malignant nature of the tumor. Thoracic radiographs are more sensitive than a thyroid scan for identifying pulmonary metastasis.

#### Diagnosis

For a definitive diagnosis to be rendered, a biopsy specimen must be obtained from the tumor and evaluated histologically. Unfortunately, canine thyroid tumors are highly vascular, and it is common for hemorrhage to occur after biopsy. Fine-needle aspiration using a 21- or 23-gauge needle and cytologic examination of the mass are recommended initially to confirm that the mass is of thyroid origin. Contamination of the aspirate with blood is common, and differentiation between adenoma and carcinoma is difficult. Large-bore needle biopsy, surgical exploration, or ultrasound-guided biopsy is often required to confirm the diagnosis. Ultrasonography identifies solid areas of the mass to

biopsy and large blood vessels to be avoided. This procedure is preferred if the findings yielded by needle aspiration are inconclusive.

#### **Treatment**

Treatment options for thyroid tumors in dogs include surgery, chemotherapy, megavoltage irradiation, radioactive iodine, and antithyroid drugs. The therapeutic approach is based, in part, on the size and invasiveness of the tumor and the presence of regional and distant metastasis. The functional status of the thyroid tumor does not dramatically alter the treatment approach. All thyroid tumors in dogs should be considered malignant until proved otherwise. Treatment is warranted even for large, locally invasive tumors. Many dogs with large invasive tumors appear more comfortable and have the potential for increased longevity after treatment. In addition, local control of the tumor may halt or reduce metastatic spread, and the presence of metastatic spread may not ultimately affect outcome. Local control of the thyroid carcinoma is of primary importance in managing this disease.

#### **SURGERY**

Surgical excision of thyroid adenomas and small, well-encapsulated, movable thyroid carcinomas is likely to be curative. Surgical removal of a fixed, invasive thyroid carcinoma, regardless of size, carries a guarded to poor prognosis for complete excision of the tumor. Megavoltage irradiation is the treatment of choice for these tumors. Chemotherapy is indicated if distant metastasis is identified. Surgical debulking of fixed, invasive tumors is indicated to relieve tumorinduced problems such as dysphagia or dyspnea and allow more time for other therapies to work. Surgical debulking may also be considered after megavoltage irradiation or chemotherapy has caused the size of large invasive tumors to shrink. Aggressive attempts at surgical removal, especially of bilateral tumors, threaten the integrity of recurrent laryngeal nerves, parathyroid glands, and normal thyroid tissue. It is important to monitor serum calcium concentrations before and for 7 to 10 days after surgery if there is any chance that the parathyroid glands have been excised or damaged. Vitamin D and calcium therapy should be initiated if any evidence of hypoparathyroidism is found (see p. 735). Serum T<sub>4</sub>, fT<sub>4</sub>, and TSH concentrations should be monitored 2 to 3 weeks after surgery and, depending on clinical signs, replacement therapy implemented accordingly (see p. 741). (See Slatter [2003] and Fossum [2007] for information on surgical techniques for the thyroparathyroid complex.)

#### **MEGAVOLTAGE IRRADIATION**

Megavoltage irradiation is the treatment of choice for locally advanced thyroid carcinoma. Megavoltage irradiation can be used alone or in conjunction with surgery or chemotherapy. There is a slow regression rate of thyroid carcinoma after radiation therapy in dogs. In one study involving 25 dogs with unresectable differentiated thyroid carcinoma and no evidence of metastasis, the time to attain maximum reduc-

tion in tumor size ranged from 8 to 22 months after megavoltage irradiation (Theon et al., 2000). Progression-free survival rates (defined as the time between completion of irradiation and detection of measurable local tumor recurrence or death from causes unrelated to tumor progression) were 80% at 1 year and 72% at 3 years with a mean progression-free survival time of 55 months in the 25 dogs. Acute radiation reactions to megavoltage irradiation include esophageal, tracheal, or laryngeal mucositis causing dysphagia, cough, and hoarseness. These reactions tend to be mild and self-limiting. Chronic radiation reactions include skin fibrosis, permanent alopecia, chronic tracheitis causing a dry cough, and hypothyroidism.

#### CHEMOTHERAPY

Chemotherapy is indicated when total surgical removal or destruction with megavoltage irradiation is not successful, if distant metastatic lesions have been identified, and if the size of the primary tumor is such that local invasion or metastasis is likely, even though it cannot be identified with diagnostic tests. Whenever the thyroid mass exceeds approximately 4 cm in diameter, the probability of metastasis becomes extremely high. Doxorubicin given at a dosage of 30 mg/m<sup>2</sup> body surface area intravenously every 3 to 6 weeks is the historic treatment of choice. The response of canine thyroid tumors to doxorubicin is variable. In most dogs doxorubicin prevents further growth of the tumor and may cause the tumor to shrink, but total remission is uncommon. Combination chemotherapy with 5-fluorouracil, cyclophosphamide, and/or vincristine may enhance the effectiveness of doxorubicin. Cisplatin or carboplatin should be considered in dogs that fail to respond to or have recurrence of disease with doxorubicin therapy. The response to cisplatin has been reported to be similar to the response to doxorubicin, although several cisplatin-treated dogs were previously treated with doxorubicin (Fineman et al., 1998). (See Chapters 77 and 78 for a discussion of the use of these chemotherapeutic agents.)

#### RADIOACTIVE IODINE (1311)

Recent retrospective studies suggest that 131 therapy will prolong survival times when used as sole therapy or in combination with surgery for the treatment of thyroid tumors in dogs. Worth et al. (2005) reported a median survival time of 30 months for dogs treated with radioiodine alone, 34 months when radioiodine was combined with surgery, and 3 months for dogs that did not receive treatment. Turrell et al. (2006) reported a median survival time of 839 days for dogs with local or regional tumors (i.e., stage II and III disease) and 366 days for dogs with metastasis. Tumor site (cervical versus ectopic), age, body weight, treatment protocol (131 alone or with surgery), and serum T<sub>4</sub> concentration were not significantly associated with survival time. Iodine 131 therapy is useful for any thyroid tumor tissue that can accumulate organic iodine, including metastatic sites. Kinetic studies to evaluate the ability of the tumor to trap iodine should be conducted before considering radioactive iodine treatment. Large doses of <sup>131</sup>I (i.e., 30 to 150 mCi) are typically administered intravenously or subcutaneously to treat canine thyroid tumors. Potential adverse reactions include esophagitis, tracheitis, and bone marrow suppression.

#### **ORAL ANTITHYROID DRUGS**

Oral antithyroid drugs are used as palliative therapy to control the clinical signs of hyperthyroidism in dogs with functional thyroid tumors. Oral antithyroid drugs are not used as a primary treatment because they are not cytotoxic. The therapeutic approach is similar to that used in hyperthyroid cats (see p. 754), beginning with 2.5 mg of methimazole administered twice a day, with subsequent increases in the dosage and frequency of administration as needed to control clinical signs and maintain the serum T<sub>4</sub> concentration within the reference range.

#### **Prognosis**

The prognosis for thyroid adenomas is excellent after surgical removal. The prognosis is guarded to good for dogs that undergo surgical resection of small, well-encapsulated carcinomas. Unfortunately, most dogs have relatively large thyroid masses, which have frequently invaded surrounding tissues or metastasized at the time of diagnosis. In these dogs aggressive therapy using multiple treatments can alleviate the clinical signs and in some cases dramatically reduce the tumor burden. The long-term prognosis, however, remains guarded to poor, with survival times typically ranging from 6 to 24 months, depending on the aggressiveness of treatment.

#### **HYPERGLYCEMIA**

#### **Etiology**

Hyperglycemia is present if the blood glucose concentration is greater than 130 mg/dl, although clinical signs of hyperglycemia do not develop until the renal tubular threshold for the resorption of glucose is exceeded. In dogs this typically occurs whenever the blood glucose concentration exceeds 180 to 220 mg/dl. The threshold for glucose resorption appears to be more variable in cats, ranging from 200 to 280 mg/dl. Glycosuria causes an osmotic diuresis, which in turn causes polyuria and polydipsia, the hallmark clinical signs of severe hyperglycemia (greater than 180 mg/dl in dogs and greater than 200 to 280 mg/dl in cats). The most common cause of hyperglycemia and glycosuria is diabetes mellitus. Severe hyperglycemia without glycosuria also occurs commonly in cats with stress-induced hyperglycemia, presumably resulting from the secretion of catecholamines and possibly lactate. Transient glycosuria (typically less than 1% on urine glucose test strips) may occur in some cats with severe or prolonged stress-induced hyperglycemia.

#### **Clinical Features**

Hyperglycemia of between 130 and 180 mg/dl (possibly as high as 280 mg/dl in cats) is clinically silent and is often an unsuspected finding encountered during blood testing for another reason. If a dog or cat with mild hyperglycemia (less than 180 mg/dl) and no glycosuria is seen because of poly-

uria and polydipsia, a disorder other than overt diabetes mellitus should be suspected. Mild hyperglycemia can occur in some dogs and cats up to 2 hours after consumption of diets containing increased quantities of monosaccharides and disaccharides, corn syrup, or propylene glycol; during intravenous (IV) administration of total parenteral nutrition fluids; in stressed, agitated, or excitable cats and dogs; in animals in the early stages of diabetes mellitus; and in animals with disorders and drugs causing insulin resistance (Box 52-1). A diagnostic evaluation for disorders causing insulin resistance is indicated if mild hyperglycemia is found to persist in a fasted, unstressed dog or cat, especially if the blood glucose concentration is increasing over time (see p. 783).

#### HYPOGLYCEMIA

#### Etiology

Hypoglycemia is present if the blood glucose concentration is less than 60 mg/dl. It typically results from the excessive use of glucose by normal cells (e.g., during periods of hyperinsulinism) or neoplastic cells, impaired hepatic gluconeogenesis and glycogenolysis (e.g., portal shunt, hepatic cirrhosis), a deficiency in diabetogenic hormones (e.g., hypocortisolism), an inadequate dietary intake of glucose and other substrates required for hepatic gluconeogenesis (e.g., anorexia in the neonate or toy breeds), or a combination of these mechanisms (e.g., sepsis; Box 52-2). Iatrogenic hypoglycemia is a common problem resulting from overzealous insulin administration in diabetic dogs and cats.

#### Causes of Hypoglycemia in Dogs and Cats

Portable blood glucose monitoring devices

Laboratory error

Prolonged storage of blood before separation of serum or plasma causes the glucose concentration to decrease at a rate of approximately 7 mg/dl/h. Glycolysis by red and white blood cells becomes even more apparent in dogs and cats with erythrocytosis, leukocytosis, or sepsis. Therefore whole blood obtained for the measurement of the glucose concentration should be separated soon after collection (within 30 minutes), and the serum or plasma should be refrigerated or frozen until the assay is performed to minimize artifactual lowering of the blood glucose concentration. Glucose determinations from separated and refrigerated plasma or serum are reliable for as long as 48 hours after the separation and refrigeration of the specimen. Alternatively, plasma can be collected in sodium fluoride tubes. Unfortunately, hemolysis is common in blood collected in sodium fluoride-treated

<sup>\*</sup>Common cause.

<sup>\*</sup> Common cause.

tubes, which can result in slight decrements in glucose values owing to methodologic problems in laboratory determinations. Blood glucose values determined by many portable home blood glucose—monitoring devices are typically lower than actual glucose values determined by bench-top methodologies, and this may result in an incorrect diagnosis of hypoglycemia. Finally, a laboratory error may also result in an incorrect value. It is wise to confirm hypoglycemia by determining the blood glucose concentration from a second blood sample and using bench-top methodology before embarking on a search for the cause of hypoglycemia.

#### **Clinical Features**

Clinical signs of hypoglycemia usually develop when the blood glucose concentration is less than 45 mg/dl, although this can be quite variable. The development of clinical signs depends on the severity and duration (acute versus chronic) of hypoglycemia and the rate of decline in the blood glucose concentration. Clinical signs are a result of neuroglycopenia and hypoglycemia-induced stimulation of the sympathoadrenal nervous system. Neuroglycopenic signs include seizures; weakness; collapse; ataxia; and, less commonly, lethargy, blindness, bizarre behavior, and coma. Signs of increased secretion of catecholamines include restlessness, nervousness, hunger, and muscle fasciculations.

Depending on the cause, the signs of hypoglycemia may be persistent or intermittent. The hallmark clinical sign of hypoglycemia (i.e., seizures) tends to be intermittent, regardless of the cause. Dogs and cats usually recover from hypoglycemic seizures within 30 seconds to 5 minutes as a result of activation of counterregulatory mechanisms (e.g., secretion of glucagon and catecholamines) that block the effects of insulin, stimulate hepatic glucose secretion, and promote an increase in the blood glucose concentration.

#### **Diagnostic Approach**

Hypoglycemia should always be confirmed before beginning diagnostic studies to identify the cause. Careful evaluation of the animal's history, physical examination findings, and results of routine blood tests (i.e., complete blood count [CBC], serum biochemistry panel, urinalysis) usually provides clues to the underlying cause. Hypoglycemia in the puppy or kitten is usually caused by idiopathic hypoglycemia, starvation, liver insufficiency (i.e., portal shunt), or sepsis. In young adult dogs or cats hypoglycemia is usually caused by liver insufficiency, hypoadrenocorticism, or sepsis. In older dogs or cats liver insufficiency,  $\beta$ -cell neoplasia, extrapancreatic neoplasia, hypoadrenocorticism, and sepsis are the most common causes.

Hypoglycemia tends to be mild (greater than 45 mg/dl) and is often an incidental finding in dogs and cats with hypoadrenocorticism or liver insufficiency. Additional clinical pathologic alterations are usually present (e.g., hyponatremia and hyperkalemia in animals with Addison's disease or increased alanine aminotransferase [ALT] activity, hypocholesterolemia, hypoalbuminemia, and a low blood urea nitrogen [BUN] concentration in animals with liver

insufficiency). An adrenocorticotropic hormone (ACTH) stimulation test or liver function test (i.e., preprandial and postprandial bile acids) may be required to confirm the diagnosis. Severe hypoglycemia (less than 40 mg/dl) may develop in neonates and juvenile kittens and puppies (especially toy breeds) and in animals with sepsis, β-cell neoplasia, and extrapancreatic neoplasia, most notably hepatic adenocarcinoma and leiomyosarcoma. Sepsis is readily identified on the basis of physical examination findings and abnormal CBC findings, such as a neutrophilic leukocytosis (typically greater than 30,000/µl), a shift toward immaturity, and signs of toxicity. Extrapancreatic neoplasia can usually be identified on the basis of the physical examination, abdominal or thoracic radiography, and abdominal ultrasonography findings. Dogs with  $\beta$ -cell neoplasia typically have normal physical examination findings and no abnormalities other than hypoglycemia identified on routine blood and urine tests. Measurement of baseline serum insulin concentration when the blood glucose is less than 60 mg/dl (preferably less than 50 mg/dl) is necessary to confirm the diagnosis of a β-cell tumor.

#### **Treatment**

Whenever possible, therapy should always be directed at eliminating the underlying cause of the hypoglycemia. If the disorder cannot be eliminated and the clinical signs of hypoglycemia persist, long-term symptomatic therapy designed to increase the blood glucose concentration may be necessary to minimize clinical signs (see Box 52-12). Such therapy is usually required for animals with metastatic  $\beta$ -cell or extrapancreatic neoplasia.

Symptomatic therapy for animals with severe hypoglycemia of acute onset relies on the administration of glucose (Box 52-3). If the dog or cat is having a hypoglycemic seizure at home, the client should rub a sugar mixture on the pet's buccal mucosa. Most animals respond within 1 to 2 minutes. Clients should be instructed never to place fingers in, or pour the sugar solution down, the pet's mouth. Once the dog or cat is sternal and cognizant of its surroundings, it should be fed a small meal and brought to the veterinarian.

If collapse, seizures, or coma develops in the hospital, a blood sample should be obtained to measure the glucose concentration and other variables before reversing the signs with the IV administration of 50% dextrose. Dextrose should be administered in small amounts slowly rather than in large boluses rapidly. This is especially important in dogs with suspected  $\beta$ -cell neoplasia in which aggressive glucose administration can result in severe hypoglycemia after excessive insulin secretion by the tumor in response to the glucose. Commonly, 2 to 15 ml of 50% dextrose is required to alleviate the signs. Dogs and cats with hypoglycemia usually respond to glucose administration within 2 minutes. Recurrence of hypoglycemia is dependent on the ability to correct the underlying etiology.

Occasionally, a dog or cat with severe central nervous system signs (e.g., blindness, coma) does not respond to initial glucose therapy. Irreversible cerebral lesions may result from prolonged severe hypoglycemia and the resultant

BOX 52-3

Medical Therapy for Acute Hypoglycemic Scizures

#### Seizures at Home

Step 1. Rub or pour sugar solution on pet's gums.

Step 2. Once pet is sternal, feed a small meal.

Step 3. Call the veterinarian.

#### Seizures in Hospital

Step 1. Administer 1 to 5 ml of 50% dextrose IV *slowly* over 10 minutes.

Step 2. Once animal is sternal, feed a small meal.

Step 3. Initiate chronic medical therapy if necessary (see Box 52-12).

#### Intractable Seizures in Hospital

Step 1. Administer 2.5% to 5% dextrose in water intravenously at 1.5 to 2 times maintenance fluid rate.

Step 2. Add 0.5 to 1 mg of dexamethasone/kg to IV fluids and administer over 6 hours; repeat every 12 to 24 hours, as necessary.

Step 3. Administer IV glucagon USP (Eli Lilly Co.) by constant-rate infusion at an initial dosage of 5 to 10 ng/kg/min (see p. 805).

Step 4. If preceding steps fail, anesthetize animal for 4 to 8 hours while continuing previously described therapy.

IV, Intravenous.

cerebral hypoxia. The prognosis in these animals is guarded to poor. Therapy is directed at providing a continuous supply of glucose by administering a 2.5% to 5% solution intravenously or increasing hepatic gluconeogenesis with a constant rate infusion of glucagons (see p. 805). Seizure activity is controlled with diazepam or a stronger anticonvulsant medication. Glucocorticoids and mannitol may be necessary to combat cerebral edema.

#### DIABETES MELLITUS IN DOGS

#### **Etiology**

Virtually all dogs with diabetes have insulin-dependent diabetes mellitus (IDDM) at the time of diagnosis. IDDM is characterized by hypoinsulinemia, essentially no increase in the endogenous serum insulin concentration after the administration of an insulin secretagogue (e.g., glucose or glucagon) at any time after the diagnosis of the disease, failure to establish glycemic control in response to diet or treatment with oral hypoglycemic drugs (or both), and an absolute need for exogenous insulin to maintain glycemic control. The cause of diabetes mellitus has been poorly characterized in dogs but is undoubtedly multifactorial. A genetic predisposition, infection, insulin-antagonistic diseases and drugs, obesity, immune-mediated insulitis, and pancreatitis have been identified as inciting factors. The end result is a loss of  $\beta$ -cell function, hypoinsulinemia, impaired transport

of circulating glucose into most cells, and accelerated hepatic gluconeogenesis and glycogenolysis. The subsequent development of hyperglycemia and glycosuria causes polyuria, polydipsia, polyphagia, and weight loss. Ketoacidosis develops as the production of ketone bodies increases to compensate for the underutilization of blood glucose (see p. 794). Loss of  $\beta$ -cell function is irreversible in dogs with IDDM, and lifelong insulin therapy is mandatory to maintain glycemic control of the diabetic state.

Unlike cats, dogs very rarely have a transient or reversible form of diabetes mellitus. The most common scenario for transient diabetes mellitus in dogs is correction of insulin antagonism after ovariohysterectomy in a bitch in diestrus. Progesterone stimulates secretion of growth hormone in the bitch. Ovariohysterectomy removes the source of progesterone, plasma growth hormone concentration declines, and insulin antagonism resolves. If an adequate population of functional β cells are still present in the pancreas, hyperglycemia may resolve without the need for insulin treatment. These dogs have a significant reduction in  $\beta$ -cell numbers (i.e., subclinical diabetes) compared with healthy dogs, before the development of hyperglycemia during diestrus, and are prone to redevelopment of hyperglycemia and diabetes mellitus if insulin antagonism recurs for any reason after ovariohysterectomy. Although uncommon, a similar situation can occur in dogs with subclinical diabetes treated with insulin-antagonistic drugs (e.g., glucocorticoids) or in the very early stages of an insulin-antagonistic disorder (e.g., hyperadrenocorticism). Failure to quickly correct the insulin antagonism will result in IDDM and the lifelong requirement for insulin treatment to control the hyperglycemia.

A honeymoon period occurs in some dogs with newly diagnosed IDDM. It is characterized by excellent glycemic control in response to small doses of insulin (less than 0.2 U/kg/injection), presumably because of the presence of residual  $\beta$ -cell function. However, glycemic control becomes more difficult and insulin doses usually increase within 3 to 6 months of starting treatment as residual functioning  $\beta$  cells are destroyed and endogenous insulin secretion declines. It is very uncommon for non–insulin-dependent diabetes mellitus (NIDDM) to be recognized clinically in dogs, despite the documentation of obesity-induced carbohydrate intolerance in dogs and the identification of residual  $\beta$ -cell function in some diabetic dogs.

#### **Clinical Features**

#### **SIGNALMENT**

Most dogs are 4 to 14 years old at the time diabetes mellitus is diagnosed, with a peak prevalence at 7 to 9 years of age. Juvenile-onset diabetes occurs in dogs younger than 1 year of age and is uncommon. Female dogs are affected about twice as frequently as male dogs. Genetic predispositions to the development of diabetes are suspected in some breeds on the basis of familial associations and pedigree analysis (Table 52-1).

**TABLE 52-1** 

Breeds Recognized to Have High and Low Risk for Developing Diabetes Mellitus Based on Analysis of the Veterinary Medical Database (VMDB) from 1970 to 1993.\*

BREEDS WITH HIGH RISK	ODDS RATIO	BREEDS WITH LOW RISK	ODDS RATIO
Australian Terrier	9.39	German Shepherd Dog <sup>†</sup>	0.18

From Guptill L et al: Is canine diabetes on the increase? In *Recent advances in clinical management of diabetes mellitus*, lams Company, Dayton, Ohio, 1999, p. 24. Mixed-breed dogs were used as the reference group (Odds Ratio 1.00) for comparison with other breeds.

\* The VMDB comprises medical records of 24 veterinary schools in the United States and Canada. VMDB case records analyzed included those from first hospital visits of 6078 dogs with a diagnosis of diabetes mellitus and 5,922 randomly selected dogs with first hospital visits for any diagnosis other than diabetes mellitus seen at the same veterinary schools in the same year. Only breeds with more than 25 cases of diabetes mellitus are included.

<sup>1</sup>Breeds also identified with significant high or low risk for developing diabetes in a study by Hess RS et al: Breed distribution of dogs with diabetes mellitus admitted to a tertiary care facility, J Am Vet Med Assoc 216:1414, 2000.

#### **HISTORY**

The history in virtually all diabetic dogs includes polydipsia, polyuria, polyphagia, and weight loss. Polyuria and polydipsia do not develop until hyperglycemia results in glycosuria. Occasionally, a client brings in a dog because of sudden blindness caused by cataract formation (Fig. 52-1). The typical clinical signs of diabetes were either unnoticed or considered irrelevant by the client. If the clinical signs associated with uncomplicated diabetes are not observed by the client and impaired vision caused by cataracts does not develop, a diabetic dog is at risk for the development of systemic signs of illness as progressive ketonemia and metabolic acidosis develop. The time sequence from the onset of initial clinical signs to the development of diabetic ketoacidosis (DKA) is unpredictable, ranging from days to weeks.

### PHYSICAL EXAMINATION

Physical examination findings depend on the presence and severity of DKA, on the duration of diabetes before its diagnosis, and on the nature of any other concurrent disorder. The nonketotic diabetic dog has no classic physical examination findings. Many diabetic dogs are obese but are otherwise in good physical condition. Dogs with prolonged untreated diabetes may have lost weight but are rarely emaciated unless concurrent disease (e.g., pancreatic exocrine insufficiency) is present. The haircoat may be sparse; the hairs may be dry,

Bilateral cataracts causing blindness in a diabetic dog. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

brittle and lusterless; and scales from hyperkeratosis may be present. Diabetes-induced hepatic lipidosis may cause hepatomegaly. Lenticular changes consistent with cataract formation are common. Additional abnormalities may be identified if DKA is present (see p. 796).

## **Diagnosis**

The diagnosis of diabetes mellitus is based on three findings: appropriate clinical signs, persistent fasting hyperglycemia, and glycosuria. Measurement of the blood glucose concentration using a portable blood glucose–monitoring device and testing for the presence of glycosuria using urine reagent test strips (e.g., KetoDiastix; Ames Division, Miles Laboratories) provides rapid confirmation of diabetes mellitus. Concurrent documentation of ketonuria establishes a diagnosis of diabetic ketosis (DK), and documentation of metabolic acidosis establishes a diagnosis of DKA.

It is important to document both persistent hyperglycemia and glycosuria to establish a diagnosis of diabetes mellitus because hyperglycemia differentiates diabetes mellitus from primary renal glycosuria and glycosuria differentiates diabetes mellitus from other causes of hyperglycemia (see Box 52-1), most notably epinephrine-induced stress hyperglycemia that may develop around the time of blood sampling. Stress-induced hyperglycemia is a common problem in cats and occasionally occurs in dogs, especially those that are very excited, hyperactive, or aggressive. The reader is referred to p. 792 for more information on stress-induced hyperglycemia.

A thorough evaluation of the dog's overall health is recommended once the diagnosis of diabetes mellitus has been established to identify any disease that may be causing or contributing to the carbohydrate intolerance (e.g., hyperadrenocorticism), that may result from the carbohydrate intolerance (e.g., bacterial cystitis), or that may mandate a modification of therapy (e.g., pancreatitis). The minimum laboratory evaluation should include a CBC, serum biochemistry panel, measurement of serum pancreatic lipase immunoreactivity, and urinalysis with bacterial culture. Serum progesterone concentration should be determined if diabetes mellitus is diagnosed in an intact bitch, regardless of her cycling history. If available, abdominal ultrasound is indicated to assess for pancreatitis, adrenomegaly, pyometritis in an intact bitch, and abnormalities affecting the liver and urinary tract (e.g., changes consistent with pyelonephritis or cystitis). Measurement of baseline serum insulin concentration or an insulin response test is not routinely done. Additional tests may be warranted after obtaining the history, performing the physical examination, or identifying ketoacidosis. Potential clinical pathologic abnormalities are listed in Box 52-4.

#### **Treatment**

The primary goal of therapy is elimination of client-observed clinical signs of diabetes. Persistence of clinical signs and development of chronic complications (Box 52-5) are directly correlated with the severity and duration of hyperglycemia. In the diabetic dog establishing control of hyperglycemia can be accomplished with insulin, diet, exercise, prevention or control of concurrent insulin antagonistic diseases, and discontinuation of medications that cause insulin resistance. The veterinarian must also guard against development of hypoglycemia, a serious and potentially fatal com-

Clinicopathologic Abnormalities Commonly Found in Dogs and Cats with Uncomplicated Diabetes Mellitus

#### **Complete Blood Count**

Typically normal

Neutrophilic leukocytosis, toxic neutrophils if pancreatitis or infection present

#### **Biochemistry Panel**

Hyperglycemia

Hypercholesterolemia

Hypertriglyceridemia (lipemia)

Increased alanine aminotransferase activity (typically <500 IU/L)

Increased alkaline phosphatase activity (typically <500 IU/L)

#### Urinalysis

Urine specific gravity typically >1.025 Glycosuria Variable ketonuria Proteinuria Bacteriuria

#### **Ancillary Tests**

Serum lipase normal or increased if pancreatitis present Serum amylase normal or increased if pancreatitis present Serum trypsinlike immunoreactivity (TLI)

Low if pancreatic exocrine insufficiency present Normal or increased if pancreatitis present

Serum canine pancreatic lipase immunoreactivity (cPU)

Normal or increased if pancreatitis present Baseline serum insulin concentration

IDDM: low, normal

NIDDM: low, normal, increased

Insulin resistance induced: low, normal, increased

IDDM, Insulin-dependent diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus.

plication of therapy. Hypoglycemia is most apt to occur as the result of overzealous insulin therapy. The veterinarian must balance the benefits of tight glucose control obtainable with aggressive insulin therapy against the risk of hypoglycemia.

## OVERVIEW OF INSULIN PREPARATIONS

Types of insulin typically used for the home treatment of diabetes in dogs and cats include intermediate-acting insulin (NPH, lente) and long-acting basal insulin (PZI, insulin glargine; (Table 52-2). NPH (Humulin N®, Eli Lilly) is a recombinant human insulin, lente (Vetsulin®, Intervet) is a purified pork-source insulin, and PZI (PZI Vet®, IDEXX) is a beef/pork-source insulin with approximately 90% being beef-source insulin. Insulin glargine (Lantus®, Aventis Pharmaceuticals) is a long-acting insulin analog in which the amino acid sequence has been altered, compared with human

Gastric paresis

Intestinal hypomotility and diarrhea

Diabetic dermatopathy (i.e., superficial necrolytic dermatitis)

insulin, making glargine more soluble at a slightly acidic pH and less soluble at a physiological pH than human insulin. The solution in the bottle of glargine is acidic, which keeps glargine soluble and suspended in the solution (i.e., the solution is clear, and the bottle does not need to be rolled before the insulin is drawn into the syringe). Because of this dependency on pH, glargine cannot be diluted or mixed with anything that may change the pH of the solution. Glargine forms microprecipitates in the subcutaneous tissue at the site of injection, from which small amounts of insulin glargine are slowly released and absorbed into the circulation. In humans the slow, sustained release of insulin glargine from these microprecipitates results in a relatively constant concentration/time profile over a 24-hour period with no pronounced peak in serum insulin. Insulin glargine is currently recommended as a basal insulin (i.e., sustained long-acting insulin used to inhibit hepatic glucose production) administered once a day at bedtime and used in conjunction with either prandial insulin analogs or oral hypoglycemic drugs in human diabetics.

#### STORAGE AND DILUTION OF INSULIN

Freezing, heating, and shaking the insulin bottle inactivate insulin in the bottle. Although keeping the substance at "room temperature": does not inactivate insulin, I instruct clients to store insulin in the door of the refrigerator to maintain a consistent environment and prolong the life of

Table 52-2

Commonly Used Insulin Preparations for Treating Diabetes in Dogs and Cats

		ADMINISTRATIO	N	TYPICAL DI	JRATION T (hr)	OF

PZI	90% beef 10% pork	Treat diabetes at home Good initial insulin for cats	SC	q12h	_	10-14	Induction of insulin antibodies in dogs
Glargine	Insulin analog	Treat diabetes at home Good initial insulin for cats	SC	q12-24h	10-16	10-16	Duration of effect too long for q12h therapy in some cats

the insulin preparation. Some veterinarians advocate replacing insulin with a new bottle every month to prevent problems caused by loss of activity or sterility. I have not appreciated a clinically significant loss of insulin action with time when insulin preparations, including glargine, are maintained in a constant environment (i.e., refrigerator) and handled appropriately. I do not routinely recommend purchasing a new bottle of insulin every month, especially if the diabetic dog or cat is doing well. However, development of cloudiness or discoloration suggest contamination, change in pH of the solution (glargine), and/or loss of insulin activity. The vial of insulin should be discarded and replaced with a new bottle of insulin. Similarly, loss of insulin activity in the bottle should always be considered whenever clinical signs recur, regardless of the quantity of insulin remaining in the bottle.

Dilution of insulin is a common practice, especially in very small dogs and cats. Although studies evaluating the shelf-life of diluted insulin have not been published, I recommend replacing diluted insulin preparations every 4 to 8 weeks. Even when these guidelines are observed, insufficient amounts of insulin are administered when diluted insulin is used in some dogs and cats, despite appropriate dilution and insulin administration techniques—inadequacies that are corrected when full-strength insulin is used. It is important to remember that insulin glargine is pH dependent and cannot be diluted.

## INITIAL INSULIN RECOMMENDATIONS FOR DIABETIC DOGS

Lente and NPH are the initial insulins of choice for treating diabetes in dogs (see Table 52-2). Recombinant humansource or pork-source insulin should be used to prevent insulin antibodies (see p. 782). My starting dosage for both types of insulin is approximately 0.25 U/kg of body weight. Because the overwhelming majority of diabetic dogs require lente or NPH insulin twice a day, the preference is to start with twice-daily insulin therapy. Establishing control of glycemia is easier and problems with hypoglycemia and the Somogyi response (see p. 780) are less likely when twicedaily insulin therapy is initiated while the insulin dose is low (i.e., at the time insulin treatment is initiated). The initial dosage recommendation (1 U/kg) on the package insert for Vetsulin® is too high. In a recent study by Monroe et al. (2005) evaluating the efficacy of Vetsulin® using the dosage recommendations on the package insert, approximately 40% of the dogs developed clinical signs of hypoglycemia at home and a blood glucose concentration of less than 60 mg/dl was identified in 36% of the dogs during generation of a blood glucose curve in the hospital.

I currently use insulin glargine in poorly controlled diabetic dogs in which NPH and lente insulin are ineffective because of problems with short duration of insulin effect. I rarely use beef/pork-source PZI insulin in dogs because of the potential for development of insulin antibodies directed against the beef insulin in the preparation that may create problems with diabetic control (see p. 782).

#### DIET

Correction of obesity and increasing the fiber content of the diet are the two most beneficial steps that can be taken to improve control of glycemia in diabetic dogs. Obesity causes insulin resistance in dogs and is an important factor accounting for variations in response to insulin therapy in diabetic dogs. Weight loss improves insulin resistance in obese diabetic dogs. Weight loss usually requires a combination of the following: restricting caloric intake, feeding low calorie-dense diets, and increasing caloric expenditure through exercise.

Diets containing increased fiber content are beneficial for treating obesity and improving control of glycemia in diabetics dogs. The ability of the fiber to form a viscous gel appears to be of greatest importance in slowing intestinal glucose absorption. More viscous soluble fibers (e.g., gums, pectin) slow glucose absorption to a greater degree than less viscous insoluble fibers (e.g., cellulose, peanut hulls) and, as such, are believed to be of greater benefit in improving control of glycemia. Most commercial high-fiber diets predominantly contain insoluble fiber, although diets containing mixtures of soluble and insoluble fiber are becoming available. The amount of fiber varies considerably among products, ranging from 3% to 25% of dry matter (normal diets contain less than 2% fiber on a dry matter basis). In general, diets containing 12% or more insoluble fiber or 8% or more of a mixture of soluble and insoluble fiber are most likely to be effective in improving glycemic control in diabetic dogs (Box 52-6).

The dog's susceptibility to the complications of high-fiber diets, its body weight and condition, and the presence of a concurrent disease (e.g., pancreatitis, renal failure) in which diet is an important aspect of therapy ultimately dictate which, if any, fiber diet is fed. Common clinical complications of diets high in insoluble fiber include excessive frequency of defecation, constipation and obstipation, hypoglycemia 1 to 2 weeks after the increase in fiber content of the diet, and refusal to eat the diet. Complications of soluble fiber-containing diets include soft-to-watery stools, excessive flatulence, hypoglycemia 1 to 2 weeks after the increase in fiber content of the diet, and refusal to eat the diet. If firm stools or constipation becomes a problem with diets that are high in insoluble fiber, a mixture of insolubleand soluble-fiber diets can be fed or soluble fiber (e.g., psyllium, canned pumpkin) can be added to the diet to soften the stool. If soft or watery diarrhea or flatulence becomes a problem with soluble fiber-containing diets, an insolublefiber diet can be added and the quantity of the soluble-fiber diet decreased. If palatability is a problem initially, the animal can be gradually switched from its regular diet to a diet containing small amounts of fiber, after which diets containing more fiber are provided. Refusal to consume high-fiber diets months after their initiation is usually a result of boredom with the food. Periodic changes in the types of high-fiber diets and mixtures of diets have been helpful in alleviating this problem. Finally, high-fiber diets should not be fed to thin or emaciated diabetic dogs until control of glycemia is established and a normal body weight attained

## Recommendations for Dietary Treatment of Diabetes Mellitus in Dogs and Cats

Correct obesity and maintain body weight in an acceptable range (see Chapter 54).

Control daily caloric intake.

Increase daily exercise.

Avoid excessive amounts of insulin.

Maintain consistency in the timing and caloric content of the meals.

Feed within the time frame of insulin action.

Feed one half the daily caloric intake at the time of each insulin injection with q12h insulin therapy or at the time of the insulin injection and 8 to 10 hours later with q24h insulin therapy.

Minimize the impact of food on postprandial blood glucose concentrations.

Avoid monosaccharides and disaccharides, propylene glycol, and corn syrup.

Let "nibbler" cats and dogs nibble throughout the day and night; ensure that other pets do not have access to the food. Increase the fiber content of the diet (dogs).

Feed high-protein, low-carbohydrate diets (cats).

using a higher-calorie-dense, lower-fiber diet designed for maintenance.

#### **EXERCISE**

Exercise plays an important role in maintaining glycemic control in the diabetic dog by helping promote weight loss and eliminating the insulin resistance induced by obesity. Exercise also has a glucose-lowering effect by increasing the mobilization of insulin from its injection site, presumably resulting from increased blood and lymph flow, by increasing blood flow (and therefore insulin delivery) to exercising muscles, and by stimulating glucose transporters in muscle cells. The daily routine for diabetic dogs should include exercise, preferably at the same time each day. Strenuous and sporadic exercise can cause severe hypoglycemia and should be avoided. If unavoidable, the insulin dose should be decreased in dogs subjected to sporadic strenuous exercise on those days of anticipated increased exercise. The reduction in insulin dose required to prevent hypoglycemia is variable and determined by trial and error. Reducing the insulin dose by 50% initially is recommended with further adjustments based on the occurrence of symptomatic hypoglycemia and the severity of polyuria and polydipsia that develops during the ensuing 24 to 48 hours. In addition, clients must be aware of the signs of hypoglycemia and have a source of glucose readily available to give their dog should any of these signs develop.

## IDENTIFICATION AND CONTROL OF CONCURRENT PROBLEMS

Concurrent disease and insulin-antagonistic drugs can interfere with tissue responsiveness to insulin, resulting in insulin resistance and poor control of the diabetes. Concurrent disease and insulin-antagonistic drugs typically cause insulin resistance by altering insulin metabolism (prereceptor problem), by decreasing the concentration or binding affinity of insulin receptors on the cell membrane (receptor problem), by interfering with the insulin receptor signaling cascade (postreceptor problem), or by a combination of these. Depending on the etiology, insulin resistance may be mild and easily overcome by increasing the dose of insulin (e.g., obesity); may be severe, causing sustained and marked hyperglycemia regardless of the type and dose of insulin administered (e.g., hyperadrenocorticism); or may fluctuate in severity over time (e.g., chronic pancreatitis; Box 52-7). Some causes of insulin resistance are readily apparent at the time diabetes is diagnosed, such as obesity and the administration of insulin-antagonistic drugs (e.g., glucocorticoids). Other causes of insulin resistance are not readily apparent and require an extensive diagnostic evaluation to be identified. In general, any concurrent inflammatory, infectious, hormonal, or neoplastic disorder can cause insulin resistance and interfere with the effectiveness of insulin therapy. Identification and treatment of concurrent disease play integral roles in the successful management of the dia-

### Recognized Causes of Insulin Resistance in Diabetic Dogs and Cats

### Disorders Typically Causing Severe Insulin Resistance

Hyperadrenocorticism Acramegaly (cat)

Progesterone excess (diestrus in female dog)

Renal insufficiency Liver insufficiency Cardiac insufficiency Hypothyroidism Hyperthyroidism

Pancreatic exocrine insufficiency

Hyperlipidemia Neoplasia Glucagonoma Pheochromocytom

betic dog. A thorough history, physical examination, and complete diagnostic evaluation are imperative in the newly diagnosed diabetic dog (see the section on diagnosis, p. 769).

## PROTOCOL FOR IDENTIFYING INITIAL INSULIN REQUIREMENTS

Diabetic dogs require several days to equilibrate to changes in insulin dose or preparation. Therefore newly diagnosed diabetic dogs are typically hospitalized for no more than 24 to 48 hours to finish the diagnostic evaluation of the dog and begin insulin therapy. During hospitalization blood glucose concentrations are typically determined at the time insulin is administered and 3, 6, and 9 hours later. The intent is to identify hypoglycemia (i.e., blood glucose less than 80 mg/ dl) in those dogs that are unusually sensitive to the actions of insulin. If hypoglycemia occurs, the insulin dose is decreased before sending the dog home. The insulin dose is not adjusted in those dogs that remain hyperglycemic during the first few days of insulin therapy. The objective during this first visit is not to establish perfect glycemic control before sending the dog home. Rather, the objective is to begin to reverse the metabolic derangements induced by the disease, allow the patient to equilibrate to the insulin and change in diet, teach the client how to administer insulin, and give the client a few days to become accustomed to treating the diabetic dog at home. Adjustments in insulin therapy are made on subsequent evaluations, once the client and pet have become accustomed to the treatment regimen.

Diabetic dogs are typically evaluated once weekly until an effective insulin treatment protocol is identified. Glycemic control is attained when clinical signs of diabetes have resolved; the pet is healthy and interactive in the home; its body weight is stable (unless the dog is undergoing weight loss to correct obesity); the client is satisfied with the prog-

ress of therapy; and, if possible, the blood glucose concentrations range between 100 and 250 mg/dl throughout the day. The client is informed at the time insulin therapy is initiated that it will take approximately 1 month to establish a satisfactory insulin treatment protocol, assuming unidentified insulin-antagonistic disease is not present. The goals of therapy are also explained to the client. During this month changes in insulin dose, type, and frequency of administration are common and should be anticipated by the client. At each evaluation the client's subjective opinion of water intake, urine output, and overall health of the pet is discussed; a complete physical examination is performed; change in body weight noted; and serial blood glucose measurements obtained over an 8- to 12-hour period after insulin administration are assessed. Adjustments in insulin therapy are based on this information, the pet is sent home, and an appointment is scheduled for the next week to reevaluate the response to any change in therapy. If the dog remains poorly controlled, the dose of insulin is gradually increased by 1 to 5 U/injection (depending on the size of the dog) each week until control is attained. This gradual increase in dose helps prevent hypoglycemia and the Somogyi response. Control of glycemia can be established in most dogs using insulin doses in the range of 1.0 U of insulin/kg or less administered twice each day. If the insulin dose exceeds 1.5 U/kg/injection without adequate glycemic control, then further investigations to determine the reason for treatment failure are indicated (see the section on complications of insulin therapy, p. 779). If hypoglycemia is noted either clinically or biochemically at any time, the insulin dosage should be decreased and further adjustments in the insulin dose performed as needed to attain glycemic control.

Many factors affect the dog's glycemic control from day to day, including variations in insulin administration and absorption, dietary indiscretions and caloric intake, amount of exercise, and variables that affect insulin responsiveness (e.g., stress, concurrent inflammation, infection). As a consequence, the insulin dosage required to maintain glycemic control typically changes with time. Initially, a fixed dose of insulin is administered at home and changes are made only after the client consults with the veterinarian. As the insulin dose range required to maintain glycemic control becomes apparent and as confidence is gained in the client's ability to recognize signs of hypoglycemia and hyperglycemia, the client is eventually allowed to make slight adjustments in the insulin dose at home on the basis of clinical observations of the pet's well-being. However, the client is instructed to stay within the agreed-upon insulin dose range. If the insulin dose is at the upper or lower end of the established range and the pet is still symptomatic, the client is instructed to call the veterinarian before making further adjustments in the insulin dose.

## **Techniques for Monitoring Diabetic Control**

The basic objective of insulin therapy is to eliminate the clinical signs of diabetes mellitus while avoiding the common complications associated with the disease (see Box 52-5). Common complications in dogs include blindness caused by cataract formation, weight loss, hypoglycemia, recurring ketosis, and recurrence of polyuria and polydipsia. The devastating chronic complications of human diabetes (e.g., nephropathy, vasculopathy, coronary artery disease) require several decades to develop and are uncommon in diabetic dogs. As such, the need to establish nearly normal blood glucose concentrations is not necessary in diabetic dogs. Generally speaking, most clients are happy and most dogs are healthy and relatively asymptomatic if blood glucose concentrations are kept between 100 and 250 mg/dl.

### HISTORY AND PHYSICAL EXAMINATION

The most important initial parameters for assessing control of glycemia are the client's subjective opinion of severity of clinical signs and overall health of the pet, findings on physical examination, and stability of body weight. If the client is happy with results of treatment, the physical examination is supportive of good glycemic control, and the body weight is stable, the diabetic dog is usually adequately controlled. Measurement of serum fructosamine concentration can add further objective evidence for status of glycemic control (discussed in more detail later). Poor control of glycemia should he suspected and additional diagnostics or a change in insulin therapy considered if the client reports clinical signs suggestive of hyperglycemia or hypoglycemia, the physical examination identifies problems consistent with poor control of glycemia (e.g., thin appearance, poor haircoat), or the dog is losing weight.

## SINGLE BLOOD GLUCOSE DETERMINATION

Measuring a single blood glucose concentration is helpful only if hypoglycemia is identified. Documenting hypoglycemia supports insulin overdosage and the need to decrease the insulin dose, especially if glycemic control is poor (see the discussion of the Somogyi response, p. 780). In contrast, documenting an increased blood glucose concentration does not, by itself, confirm poor control of glycemia. Stress or excitement can cause marked hyperglycemia, which does not reflect the dog's responsiveness to insulin and can lead to the erroneous belief that the diabetic dog is poorly controlled. If a discrepancy exists between the history, physical examination findings, and blood glucose concentration or if the dog is fractious, aggressive, excited, or scared and the blood glucose concentration is known to be unreliable, measurement of serum fructosamine concentration should be done to further evaluate status of glycemic control. In addition, a single blood glucose concentration is not reliable for evaluating the effect of a given insulin type and dose in a poorly controlled diabetic dog (see the section on serial blood glucose curve).

## SERUM FRUCTOSAMINE CONCENTRATION

Fructosamines are glycated proteins that result from an irreversible, nonenzymatic, insulin-independent binding of glucose to serum proteins. The extent of glycosylation of serum proteins is directly related to the blood glucose concentration; the higher the average blood glucose concentration during the preceding 2 to 3 weeks, the higher the serum fructosamine concentration, and vice versa. Serum fructosamine concentration is not affected by acute increases in the blood glucose concentration, as occurs with stress- or excitement-induced hyperglycemia, but can be affected by concurrent hypoalbuminemia (less than 2.5 g/dl), hyperlipidemia (triglycerides greater than 150 mg/dl), or hyperthyroidism (Table 52-3). Serum fructosamine concentrations can be measured during the routine evaluation of glycemic control performed every 3 to 6 months; to clarify the effect of stress or excitement on blood glucose concentrations; to clarify discrepancies between the history, physical examination findings, and serial blood glucose concentrations; and to assess the effectiveness of changes in insulin therapy.

Fructosamine is measured in serum, which should be frozen and shipped on cold packs overnight to the laboratory. Storage of serum at room temperature overnight can decrease serum fructosamine results by 10%. Each laboratory should furnish its own reference range. In our laboratory the normal reference range for serum fructosamine in dogs is 225 to 375 µmol/L; a range determined in healthy dogs with persistently normal blood glucose concentrations. Interpretation of serum fructosamine in a diabetic dog must take into consideration the fact that hyperglycemia is common, even in well-controlled diabetic dogs (see Table 52-3). Most clients are happy with the pet's response to insulin treatment if serum fructosamine concentrations can be kept between 350 and 450 µmol/L. Values greater than 500 µmol/L suggest inadequate control of the diabetic state, and values greater than 600 µmol/L indicate serious lack of glycemic control. Serum fructosamine concentrations in the

**TABLE 52-3** 

Sample Handling, Methodology, and Normal Values for Serum Fructosamine Concentrations Measured in Our Laboratory

	FRUCTOSAMINE
Blood sample	1-2 ml; allow to clot, obtain serum
Sample handling	Freeze until assayed
Methodology	Automated colorimetric assay using nitroblue tetrazolium chloride
Factors affecting results	Hypoalbuminemia (decreased), hyperlipidemia (mild decrease—dogs), azotemia (mild decrease—dogs), hyperthyroidism (decreased—cats), storage at room temperature (decreased)
Normal range	225 to 375 μmol/L (dogs) 190 to 365 μmol/L (cats)
Interpretation in Diabetic Dogs	and Cats
e II	272.402

Excellent control	350-400 μmol/L
Good control	400-450 μmol/L
Fair control	450-500 μmol/L
Poor control	>500 µmol/L
Prolonged hypoglycemia	<300 μmol/L

lower half of the normal reference range (i.e., less than 300 µmol/L) or below the normal reference range should raise concern for significant periods of hypoglycemia in the diabetic dog. Increased serum fructosamine concentrations (i.e., >500 µmol/L) suggest poor control of glycemia and a need for insulin adjustments but do not identify the underlying problem.

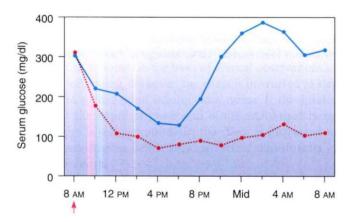

### URINE GLUCOSE MONITORING

Occasional monitoring of urine for glycosuria and ketonuria is helpful in diabetic dogs that have problems with recurring ketosis or hypoglycemia to identify ketonuria or persistent negative glycosuria, respectively. The client is instructed not to adjust daily insulin doses on the basis of morning urine glucose measurements, except to decrease the insulin dose in dogs with recurring hypoglycemia and persistent negative glycosuria. The vast majority of diabetic dogs develop complications because clients were misled by morning urine glucose concentrations. Persistent glycosuria throughout the day and night suggests inadequate control of the diabetic state and the need for a more complete evaluation of diabetic control using other techniques discussed in this section.

### SERIAL BLOOD GLUCOSE CURVES

If an adjustment in insulin therapy is deemed necessary after review of the history, physical examination, changes in body weight, and serum fructosamine concentration, then a serial blood glucose curve should be generated to provide guidance in making the adjustment, unless blood glucose measurements are unreliable because of stress, aggression, or excitement. The serial blood glucose curve provides guidelines for making adjustments in insulin therapy. Evaluation of a serial blood glucose curve is mandatory during the initial regulation of the diabetic dog and is necessary in the dog in which clinical manifestations of hyperglycemia or hypoglycemia have developed. Reliance on history, physical examination, body weight, and serum fructosamine concentration to determine when a blood glucose curve is needed helps reduce the frequency with which blood glucose curves must be performed, thereby minimizing the animal's aversion to these evaluations and improving the chances of obtaining meaningful results when a blood glucose curve is needed.

When a blood glucose curve is being generated, the insulin and feeding schedule used by the client should be maintained, the dog dropped off at the hospital early in the morning, and blood obtained every 1 to 2 hours throughout the day for glucose determination. It is more important to maintain the pet's daily routine than to risk inaccurate blood glucose results caused by inappetence in the hospital or insulin administration at an unusual time (Fig. 52-2). If there are concerns regarding the client's technique for administering insulin, the client can administer insulin (using his or her own insulin and syringe) in the hospital after the initial blood glucose is obtained or can demonstrate his or her technique using sterile saline after arriving to pick up the pet at the end of the day. The veterinarian or a veterinary technician should closely evaluate the entire insulin administration procedure. By measuring blood glucose concentration every 1 to 2 hours throughout the day, the clinician will be able to determine if the insulin is effective and identify the glucose nadir, time of peak insulin effect, duration of insulin effect, and severity of fluctuation in blood glucose concentrations in that particular dog. Determining the glucose nadir and the time of the glucose nadir in relation to the time of insulin administration is critical for assessing the duration of insulin effect. If the glucose nadir has not been identified by the time of the next insulin injection, the glucose curve should be continued, the scheduled insulin injection aborted, and the dog fed its evening meal (see the discussion of the prolonged duration of insulin effect, p. 781). Obtaining only 1 or 2 blood glucose concentrations has not been reliable for evaluating the effect of a given insulin dose (Fig. 52-3). Persistent poor control of the dia-

Mean blood glucose concentrations in eight diabetic dogs after the administration of NPH insulin (1) and the feeding of equal-sized meals at 8 AM and 6 PM (blue line) or feeding them nothing (red line) during the 24 hours of blood sampling.

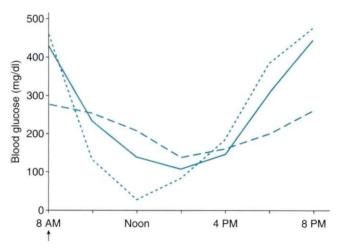

FIG 52-3

Blood glucose concentration curve in a Dachshund receiving 0.8 U of recombinant human lente insulin per kilogram of body weight twice a day (solid line), a Miniature Poodle receiving 0.6 U of recombinant human lente insulin per kilogram of body weight twice a day (dashed line), and a Terrier-mix receiving 1.1 U of recombinant human lente insulin per kilogram of body weight twice a day (dotted line). Insulin and food was given to each dog at 8 AM. Interpretation of the blood glucose curves suggest short duration of insulin effect in the Dachshund, insulin underdosing in the Miniature Poodle, and the Somogyi response in the Terrier-mix. The blood glucose concentrations were similar in all dogs at 2 PM and 4 PM; the glucose results at these times do not establish the diagnosis in any of the dogs.

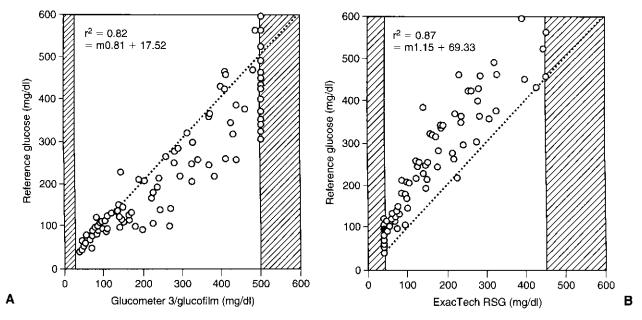

betic state often stems from misinterpretation of the effects of insulin that is based on assessment of only 1 or 2 blood glucose concentrations.

Blood glucose concentrations are typically determined by a point-of-care glucose analyzer or hand-held portable blood glucose monitoring device. Commercially available portable blood glucose-monitoring devices provide blood glucose concentrations that are reasonably close to those obtained with reference methods, although results often overestimate or underestimate actual glucose values. Blood glucose values determined by most portable blood glucose monitoring devices are typically lower than actual glucose values determined by reference methods (Fig. 52-4). This may result in an incorrect diagnosis of hypoglycemia or the misperception that glycemic control is better than it actually is. Failure to consider this error could result in insulin underdosage and the potential for persistence of clinical signs despite apparently acceptable blood glucose results. One exception is the AlphaTRAK® by Abbott Laboratories. Accuracy of this portable glucometer is very good, but glucose values may be higher or lower than glucose values measured by benchtop methodologies on the same blood sample, forcing the veterinarian to accept the blood glucose concentration at face

Insulin therapy is adjusted according to interpretation of a single serial blood glucose curve, and the impact of the change is initially assessed by client perceptions of clinical response and change in serum fructosamine concentration. If problems persist, the blood glucose curve can be repeated. If possible, performing blood glucose curves on multiple, consecutive days should be avoided because it promotes stress-induced hyperglycemia. Information gained from a prior serial blood glucose curve should never be assumed to be reproducible on subsequent curves. Lack of consistency in the results of serial blood glucose curves is a source of frustration for many veterinarians. This lack of consistency is a direct reflection of all the variables that affect the blood glucose concentration in diabetics. Daily self-monitoring of blood glucose concentrations and adjustments in insulin dose are used in human diabetics to minimize the effect of these variables on control of glycemia. A similar approach for diabetic dogs and cats will undoubtedly become more common in the future, as home glucose monitoring techniques are refined. For now, initial assessment of control of glycemia is based on the client's perception of the diabetic pet's health combined with periodic examinations by the veterinarian. Serial blood glucose measurements are indicated if poor control of glycemia is suspected. The goal of serial blood glucose measurements is to obtain a glimpse of the actions of insulin in that diabetic animal and identify a possible reason that the diabetic dog is poorly controlled.

## Protocol for Generating the Serial Blood Glucose Curve at Home

Hyperglycemia induced by stress, aggression, or excitement is the single biggest problem affecting accuracy of the serial blood glucose curve, especially in cats (Fig. 52-5). The biggest

#### FIG 52-4

Scatter plots of blood glucose concentrations obtained with two portable blood-glucose meters versus concentrations obtained using a reference method. Data represent 110 blood samples from 34 dogs. Shaded areas represent concentrations greater than or less than the concentrations that can be detected by each meter. The dashed line represents the theoretical line of equality. Note that one glucose meter tends to read higher (A) and one glucose meter tends to read lower (B) than the reference concentration. (From Cohn LA et al: Assessment of five portable blood glucose meters, a point-of-care analyzer, and color test strips for measuring blood glucose concentration in dogs, J Am Vet Med Assoc 216:198, 2000.)

factors inducing stress-induced hyperglycemia are hospitalization and multiple venipunctures. An alternative to hospital-generated blood glucose curves is to have the client generate the blood glucose curve at home using the ear or lip prick technique and a portable home glucose-monitoring device that allows the client to touch the drop of blood on the ear or lip with the end of the glucose test strip. This technique is usually reserved for diabetic dogs in which the reliability of blood glucose results generated in the veterinary hospital is questionable. The reader is referred to p. 792 for more information on monitoring blood glucose concentrations at home.

#### Interpreting the Serial Blood Glucose Curve

An overview of interpreting results of a serial blood glucose curve is provided in Fig. 52-6. The *ideal* goal is to maintain the blood glucose concentration between 100 mg/dl and 250 mg/dl throughout the day and night, although many diabetic dogs do well despite blood glucose concentrations consistently in the high 100's to low 300's. Typically, the highest blood glucose concentrations occur at the time of each insulin injection, but this does not always occur. If the blood glucose nadir is greater than 150 mg/dl, the insulin dose may need to be increased, and if the nadir is less than 80 mg/dl, the insulin dose should be decreased.

Duration of insulin effect can be assessed if the glucose nadir is greater than 80 mg/dl and there has not been a rapid decrease in the blood glucose concentration after insulin administration. Assessment of duration of insulin effect may not be valid when the blood glucose decreases to less than 80 mg/dl or decreases rapidly because of the potential induction of the Somogyi response, which can falsely decrease the apparent duration of insulin effect (see p. 780). A rough approximation of the duration of effect of insulin can be gained by examining the time of the glucose nadir. For most well-controlled diabetic dogs, the initial blood glucose concentration near the time of insulin administration is less than 300 mg/dl and the glucose nadir occurs 8 to 10 hours after injection of insulin. An initial blood glucose concentration greater than 300 mg/dl, combined with a glucose nadir occurring less than 8 hours after insulin administration and subsequent blood glucose concentrations exceeding 250 mg/ dl, is supportive of short duration of insulin effect (see p. 781). A glucose nadir occurring 12 hours or longer after insulin administration is supportive of prolonged duration of insulin effect (see p. 781). Dogs may develop hypoglycemia or the Somogyi response if the duration of insulin effect is greater than 14 hours and the insulin is being administered twice a day (Fig. 52-7).

## Role of Serum Fructosamine in Aggressive, Excitable, or Stressed Dogs

Blood glucose curves are unreliable in aggressive, excitable, or stressed dogs because of problems related to stress-induced

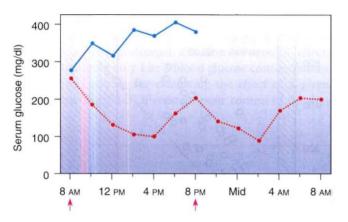

FIG 52-5

Blood glucose concentration curves in a fractious Terriermix. The same dose of NPH insulin was given for each curve. One glucose curve (blue line) was obtained with the dog in an agitated state requiring physical restraint each time a blood specimen was obtained; blood for the other glucose curve (red line) was obtained through a jugular catheter with minimal-to-no restraint and the dog in a quiet state. 1, Insulin administration and food.

hyperglycemia. In these dogs the clinician must make an educated guess as to where the problem lies (e.g., wrong type of insulin, low dose), make an adjustment in therapy, and rely on changes in serum fructosamine to assess the benefit of the change in treatment. The reader is referred to p. 792 for more information on the use of serum fructosamine in diabetic pets with stress-induced hyperglycemia.

#### **INSULIN THERAPY DURING SURGERY**

Generally, surgery should be delayed in diabetic dogs until the animal's clinical condition is stable and the diabetic state is controlled with insulin. The exception are those situations in which surgery is required to eliminate insulin resistance (e.g., ovariohysterectomy in a diestrus bitch) or to save the animal's life. The surgery itself does not pose a greater risk in a stable diabetic animal than in a nondiabetic animal. The concern is the interplay between insulin therapy and the lack of food intake during the perioperative period. The stress of anesthesia and surgery also causes the release of diabetogenic hormones, which promote ketogenesis. Insulin must be administered during the perioperative period to prevent

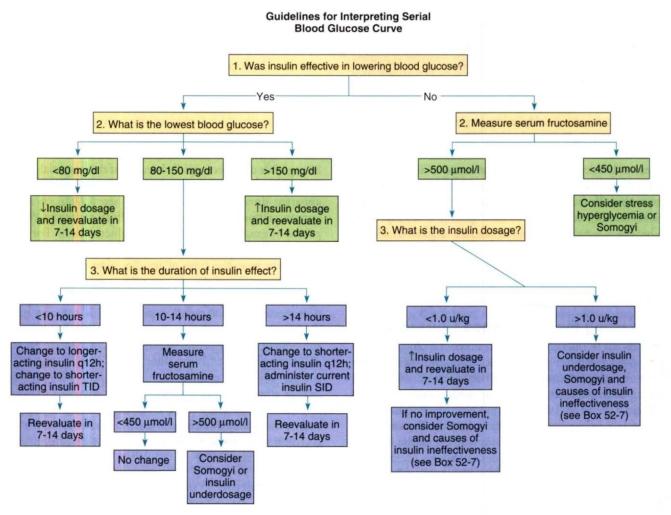

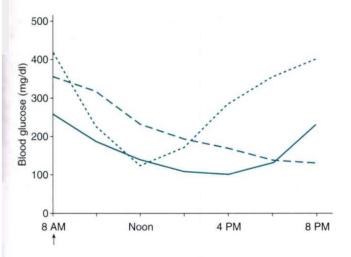

FIG 52-6
Algorithm for interpreting results of a blood glucose concentration curve.

#### FIG 52-7

Blood glucose concentration curves obtained from three diabetic dogs treated with recombinant human lente insulin twice a day, illustrating a difference between dogs in the duration of insulin effect. The insulin is effective in lowering the blood glucose concentration in all dogs, and the blood glucose nadir is between 100 and 175 mg/dl for the dogs. However, the duration of insulin effect is approximately 12 hours (solid line) in one dog with good control of glycemia (ideal duration of effect), approximately 8 hours (dotted line) in one dog with persistently poor control of glycemia (short duration of effect), and greater than 12 hours (dashed line) in one dog with a history of good days and bad days of glycemic control (prolonged duration of effect)—a history suggestive of the Somogyi response (see Fig. 52-8).

severe hyperglycemia and minimize ketone formation. To compensate for the lack of food intake and prevent hypoglycemia, the amount of insulin administered during the perioperative period is decreased and IV dextrose is administered when needed.

The following protocol is used during the perioperative period in dogs and cats undergoing surgery. The day before surgery the dog or cat is given its normal dose of insulin and fed as usual. Food is withheld after 10 PM. On the morning of the procedure the blood glucose concentration is measured before the dog or cat is given insulin. If the blood glucose concentration is less than 100 mg/dl, insulin is not given and an IV infusion of 2.5% to 5% dextrose is initiated. If the blood glucose concentration is between 100 and 200 mg/dl, one quarter of the animal's usual morning dose of insulin is given and an IV infusion of dextrose is initiated. If the blood glucose concentration is more than 200 mg/dl, one half of the usual morning dose of insulin is given but the IV dextrose infusion is withheld until the blood glucose concentration is less than 150 mg/dl. In all three situations the blood glucose concentration is measured every 30 to 60 minutes during the surgical procedure. The goal is to maintain the blood glucose concentration between 150 and 250 mg/dl during the perioperative period. A 2.5% to 5% dextrose infusion is administered intravenously as needed to correct or prevent hypoglycemia.

When the blood glucose concentration exceeds 300 mg/dl, the dextrose infusion should be discontinued and the blood glucose concentration evaluated 30 and 60 minutes later. If the blood glucose concentration remains greater than 300 mg/dl, regular crystalline insulin is administered intramuscularly at approximately 20% of the dose of long-acting insulin being used at home. Subsequent doses of regular crystalline insulin should be given no more frequently than every 4 hours, and the dose should be adjusted on the basis of the effect of the first insulin injection on the blood glucose concentration.

On the day after surgery the diabetic dog or cat can usually be returned to the routine schedule of insulin administration and feeding. An animal that is not eating can be maintained with IV dextrose infusions and regular crystalline insulin injections given subcutaneously every 6 to 8 hours. Once the animal is eating regularly, it can be returned to its normal insulin and feeding schedule.

# **COMPLICATIONS OF INSULIN THERAPY** Hypoglycemia

Hypoglycemia is a common complication of insulin therapy. Signs of hypoglycemia are most apt to occur after sudden large increases in the insulin dose, with excessive overlap of insulin action in dogs receiving insulin twice a day, after prolonged inappetence, during unusually strenuous exercise, following sudden improvement in concurrent insulin resistance, and in insulin-treated cats that have reverted to a non-insulin-dependent state (see p. 785). In these situations severe hypoglycemia may occur before glucose counterregulation (i.e., secretion of glucagon, epinephrine, cortisol, and growth hormone) is able to compensate for and reverse hypoglycemia. The occurrence and severity of clinical signs is dependent on the rate of blood glucose decline and the severity of hypoglycemia. In many diabetic dogs signs of hypoglycemia are not apparent to clients, and hypoglycemia is identified during evaluation of a serial blood glucose curve or suspected when a low serum fructosamine concentration is identified. Clinical signs and treatment of hypoglycemia are discussed on p. 765. If clinical signs of hypoglycemia have occurred, insulin therapy should be stopped until hyperglycemia and glycosuria recur. The adjustment in the insulin dose is somewhat arbitrary; as a general rule of thumb, the insulin dose initially should be decreased 25% to 50% and subsequent adjustments in the dose based on clinical response and results of blood glucose measurements. Failure of glycosuria to recur after a hypoglycemic episode suggests reversion to a non-insulin-dependent diabetic state or impaired glucose counterregulation.

### **Recurrence of Clinical Signs**

Recurrence or persistence of clinical signs is perhaps the most common complication of insulin therapy in diabetic dogs. This is usually caused by problems with client technique in administering insulin; problems with insulin therapy relating to the insulin type, dose, species, or frequency of administration; or problems with responsiveness

to insulin caused by concurrent inflammatory, infectious, neoplastic, or hormonal disorders (i.e., insulin resistance).

**Problems with client administration and insulin activity.** Failure to administer an appropriate dose of biologically active insulin will result in recurrence or persistence of clinical signs. Common reasons include administration of biologically inactive insulin (e.g., outdated, overheated, previously frozen, destroyed by shaking the bottle), administration of diluted insulin, use of inappropriate insulin syringes for the concentration of insulin (e.g., U100 syringe with U40 insulin), or problems with insulin administration technique (e.g., failure to correctly read the insulin syringe, inappropriate injection technique). These problems are identified by evaluating the client's insulin administration technique and by administering new, undiluted insulin and measuring several blood glucose concentrations throughout the day.

**Problems with the insulin treatment regimen.** The most common problems with the insulin treatment regimen in the dog include insulin underdosage, insulin overdosage causing the Somogyi response, short duration of effect of lente or NPH insulin, and once-daily insulin administration. The insulin treatment regimen should be critically evaluated for possible problems in these areas and appropriate changes made in an attempt to improve insulin effectiveness, especially if the history and physical examination do not suggest a concurrent disorder causing insulin resistance.

**Diluted insulin.** Diluted insulin should be replaced with full-strength insulin. In some dogs insufficient amounts of insulin are administered when diluted insulin is used, despite appropriate dilution and insulin administration techniques. These inadequacies are corrected when full-strength insulin is used.

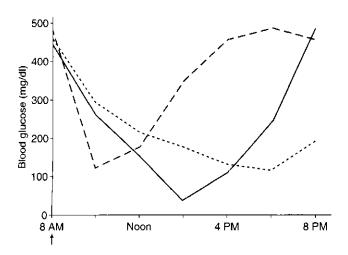

**Insulin underdosing.** Control of glycemia can be established in most dogs using less than 1.0 U of insulin/kg of body weight administered twice daily. An inadequate dose of insulin in conjunction with once-daily insulin therapy is a common cause for persistence of clinical signs. In general, insulin underdosing should be considered if the insulin dose is less than 1.0 U/kg and the animal is receiving insulin twice a day. If insulin underdosing is suspected, the dose of insulin should be gradually increased by 1 to 5 U/ injection (depending on the size of the dog) per week. The effectiveness of the change in therapy should be evaluated by client perception of clinical response and measurement of serum fructosamine or serial blood glucose concentrations. Other causes for insulin ineffectiveness, most notably the Somogyi response, should be considered once the insulin dose exceeds 1.0 to 1.5 U/kg/injection, the insulin is being administered every 12 hours, and control of glycemia remains poor.

Insulin overdosing and the Somogyi response. The Somogyi response results from a normal physiologic response to impending hypoglycemia induced by excessive insulin. When the blood glucose concentration declines to less than 65 mg/dl or when the blood glucose concentration decreases rapidly regardless of the glucose nadir, direct

hypoglycemia-induced stimulation of hepatic glycogenolysis and secretion of diabetogenic hormones, most notably epinephrine and glucagon, increase the blood glucose concentration, minimize signs of hypoglycemia, and cause marked hyperglycemia within 12 hours of glucose counterregulation. The marked hyperglycemia that occurs after hypoglycemia is due, in part, to an inability of the diabetic dog to secrete sufficient endogenous insulin to dampen the rising blood glucose concentration. By the next morning the blood glucose concentration can be extremely elevated (greater than 400 mg/dl), and the morning urine glucose concentration is consistently 1 to 2 gm/dl as measured with urine glucose test strips. Unrecognized short duration of insulin effect, combined with insulin dose adjustments based on morning urine glucose concentrations, is historically the most common cause for the Somogyi response in dogs.

Clinical signs of hypoglycemia are typically mild or not recognized by the client; clinical signs caused by hyperglycemia tend to dominate the clinical picture. The insulin dose that induces the Somogyi response is variable and unpredictable. The Somogyi response is often suspected in poorly controlled diabetic dogs in which insulin dosage is approaching 2.2 U/kg body weight/injection but can also occur at insulin dosages less than 0.5 U/kg/injection. Toy and miniature breeds of dogs are especially susceptible to development of the Somogyi response with lower-than-expected doses of insulin.

The diagnosis of the Somogyi response requires demonstration of hypoglycemia (less than 80 mg/dl) followed by hyperglycemia (greater than 300 mg/dl) after insulin administration (Fig. 52-8). The Somogyi response should also be suspected when the blood glucose concentration decreases rapidly regardless of the glucose nadir (e.g., a drop from 400 to 100 mg/dl in 2 to 3 hours). If the duration of insulin effect is greater than 12 hours, hypoglycemia often occurs at night after the evening dose of insulin and the serum glucose concentration is typically greater than 300 mg/dl the next morning. Unfortunately, the diagnosis of the Somogyi response can be elusive, in part because of the effects of the diabetogenic hormones on blood glucose concentrations after an episode of glucose counterregulation. Secretion of diabetogenic hormones during the Somogyi response may induce insulin resistance, which can last 24 to 72 hours after the hypoglycemic episode (Fig. 52-9). If a serial blood glucose curve is obtained on the day glucose counterregulation occurs, hypoglycemia will be identified and the diagnosis established. However, if the serial blood glucose curve is obtained on a day when insulin resistance predominates, hypoglycemia will not be identified and the insulin dose may be incorrectly increased in response to the high blood glucose values. A cyclic history of one or two days of good glycemic control followed by several days of poor control should raise suspicion for insulin resistance caused by glucose counterregulation. Serum fructosamine concentrations are unpredictable but are usually increased (>500 µmol/L)-results that confirm poor glycemic control but do not identify the underlying cause.

#### FIG 52-8

Blood glucose concentration curves obtained from three poorly controlled diabetic dogs treated with recombinant human lente insulin twice a day, illustrating the typical blood glucose curves suggestive of the Somogyi response. In one dog (solid line) the glucose nadir is less than 80 mg/ dl and is followed by a rapid increase in the blood glucose concentration. In one dog (dashed line) a rapid decrease in the blood glucose concentration occurs within 2 hours of insulin administration and is followed by a rapid increase in the blood glucose concentration; the rapid decrease in blood glucose stimulates glucose counterregulation, despite maintaining the blood glucose nadir above 80 mg/dl. In one dog (dotted line) the blood glucose curve is not suggestive of the Somogyi response, per se. However, the insulin injection causes the blood glucose to decrease by approximately 300 mg/dl during the day, and the blood glucose concentration at the time of the evening insulin injection is considerably lower than the 8 AM blood glucose concentration. If a similar decrease in the blood glucose occurs with the evening insulin injection, hypoglycemia and the Somogyi response would occur at night and would explain the high blood glucose concentration in the morning and the poor control of the diabetic state.

Establishing the diagnosis may require several days of hospitalization and serial blood glucose curves, an approach that eventually leads to problems with stress-induced hyperglycemia. An alternative, preferable approach is to arbitrarily reduce the insulin dose 1 to 5 units and have the client evaluate the dog's clinical response over the ensuing 2 to 5 days. If clinical signs of diabetes worsen after a reduction in the insulin dose, another cause for the insulin ineffectiveness should be pursued. However, if the client reports no change or improvement in clinical signs, continued gradual reduction of the insulin dose should be pursued. Alternatively, glycemic regulation of the diabetic dog could be started over using an insulin dose of 0.25 U/kg given twice daily.

**Short duration of insulin effect.** For most dogs, the duration of effect of lente and NPH insulin is 10 to 14 hours and twice-daily insulin administration is effective in controlling blood glucose concentrations. However, in some diabetic dogs the duration of effect of lente and NPH insulin is less than 10 hours, a duration that is too short to prevent

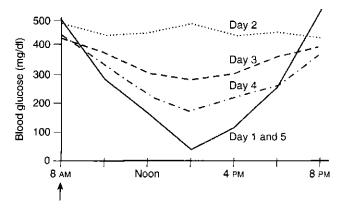

FIG 52-9

Schematic of the change in the results of blood glucose curves obtained an sequential days after induction of the Somogyi response to hypoglycemia induced by an overdose of insulin. Hypoglycemia and the Somogyi response occur on day 1. The secretion of diabetogenic hormones in response to the hypoglycemia causes insulin resistance and increased blood glucose concentrations on day 2. Insulin resistance gradually wanes over the ensuing couple of days (days 3 and 4), eventually resulting in hypoglycemia and the Somogyi response (day 5) as sensitivity to insulin returns to normal. The same dose of insulin is administered each day (arrow).

periods of hyperglycemia and persistence of clinical signs (Fig. 52-10). A diagnosis of short duration of insulin effect is made by demonstrating an initial blood glucose concentration greater than 300 mg/dl combined with a glucose nadir above 80 mg/dl that occurs less than 8 hours after insulin administration and recurrence of hyperglycemia (greater than 250 mg/dl) within 10 hours of the insulin injection (see Fig. 52-7). Treatment involves changing to a longer-acting insulin (e.g., switching to insulin glargine; Fig. 52-11) or increasing the frequency of insulin administration (e.g., initiating therapy q8h). PZI insulin of beef/pork source should not be used in dogs because of potential problems with insulin antibodies (discussed later).

Prolonged duration of insulin effect. In some diabetic dogs the duration of effect of lente or NPH insulin is greater than 12 hours, and twice-daily insulin administration creates problems with hypoglycemia and the Somogyi response. In these dogs the glucose nadir after the morning administration of insulin typically occurs near or after the time of the evening insulin administration, and the morning blood glucose concentration is usually greater than 300 mg/ dl (see Fig. 52-7). The effectiveness of insulin in lowering the blood glucose concentration is variable from day to day, presumably because of varying concentrations of diabetogenic hormones, the secretion of which was induced by prior hypoglycemia. Serum fructosamine concentrations are variable but usually greater than 500 µmol/L. An effective treatment depends, in part, on the duration of effect of the insulin. A 24-hour blood glucose curve should be generated after administration of insulin once in the morning and feeding the dog at the normal times of the day. This will

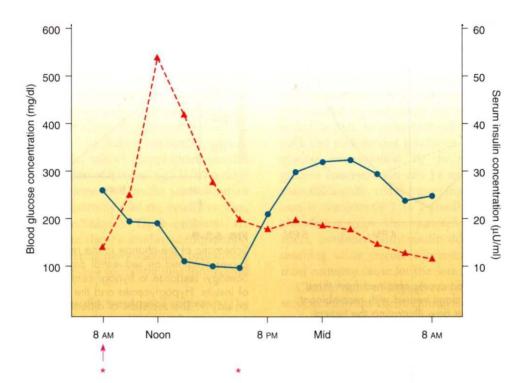

FIG 52-10

Mean blood glucose (blue line) and serum insulin (red line) concentrations in eight dogs with diabetes mellitus treated with a beef-pork source NPH insulin subcutaneously once daily. The duration of NPH effect is too short, resulting in prolonged periods of hyperglycemia beginning shortly after the evening meal. 1, Insulin injection; \*, equal-sized meals consumed.

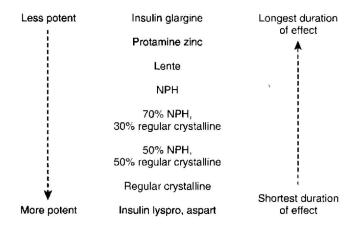

FIG 52-11
Categorization of types of commercial insulin based on the potency and duration of effect. An inverse relationship exists between the potency and duration of effect.

allow the clinician to estimate the duration of effect of the insulin. If the duration of effect is less than 16 hours, a shorter-acting insulin given twice a day or a lower dose of the same insulin given in the evening, compared with the morning insulin dose, can be tried (see Fig. 52-11). If the duration of effect is 16 hours or longer, switching to a longer-acting insulin administered once a day or administering NPH or lente insulin in the morning and regular crystalline

insulin at bedtime (i.e., 16 to 18 hours after the morning insulin injection) can be tried. When different types of insulin are used in the same 24-hour period, the goal is to have the combined duration of effect of the insulins equal 24 hours. Differences in potency of intermediate- and long-acting insulins versus regular crystalline insulin often necessitate use of different dosages for the morning and evening insulin injection; because regular crystalline insulin is more potent, less of it is required to get the same glycemic effect, compared with lente, NPH, PZI, and glargine insulin.

**Inadequate insulin absorption.** Slow or inadequate absorption of ultralente insulin was a problem in dogs and cats, but ultralente insulin is no longer commercially available. A similar problem is uncommon in diabetic dogs treated with NPH or lente insulin. Impaired absorption of insulin may also occur as a result of thickening of the skin and inflammation of the subcutaneous tissues caused by chronic injection of insulin in the same area of the body. Rotation of the injection site will help prevent this problem.

**Circulating insulin-binding antibodies.** Insulin antibodies result from repeated injections of a foreign protein (i.e., insulin). The structure and amino acid sequence of the injected insulin relative to the native endogenous insulin influence the development of insulin antibodies. Conformational insulin epitopes are believed to be more important in the development of insulin antibodies than differences in the

linear subunits of the insulin molecule, per se. The more divergent the insulin molecule being administered from the species being treated, the greater the likelihood that significant amounts of insulin antibodies will be formed. Canine, porcine, and recombinant human insulin are similar, and development of insulin antibodies is uncommon in dogs treated with porcine or recombinant human insulin. In contrast, canine and beef insulin differ and serum insulin antibodies have been identified in 40% to 65% of dogs treated with beef/pork or beef insulin. The presence of serum insulin antibodies is often associated with erratic and poor diabetic control, frequent adjustments in the insulin dose to improve control, and occasional development of severe insulin resistance. Dogs treated with porcine or recombinant human insulin have more stable control of glycemia for extended periods of time compared with dogs treated with beef insulin. Although uncommon, insulin antibodies can develop in dogs treated with recombinant human insulin and should be suspected as the cause of poor glycemic control when another cause cannot be identified. Documentation of serum insulin antibodies should make use of assays that have been validated in diabetic dogs. A switch to porcine-source insulin, a switch to a purer form of insulin (i.e., regular crystalline insulin), or both should be considered if insulin antibodies are identified in a poorly controlled diabetic dog.

Allergic reactions to insulin. Significant reactions to insulin occur in as many as 5% of human diabetics treated with insulin and include erythema, pruritus, induration, and lipoatrophy at the injection site. Allergic reactions to insulin have been poorly documented in diabetic dogs and cats. Pain on injection of insulin is usually caused by inappropriate injection technique, inappropriate site of injection, a reaction to the cold temperature of insulin stored in the refrigerator, or issues with behavior and not an adverse reaction to insulin, per se. Rarely, diabetic dogs and cats will develop focal subcutaneous edema and swelling at the site of insulin injection. Insulin allergy is suspected in these animals. Treatment includes switching to a less antigenic insulin and to a more purified insulin preparation (e.g., regular crystalline insulin). Systemic allergic reactions to insulin in dogs or cats have vet to be identified.

Concurrent disorders causing insulin resistance. Insulin resistance is a condition in which a normal amount of insulin produces a subnormal biologic response. Insulin resistance may result from problems occurring before the interaction of insulin with its receptor, at the receptor, or at steps distal to the interaction of insulin and its receptor. No insulin dose clearly defines insulin resistance. For most diabetic dogs control of glycemia can usually be attained using 1.0 U or less of NPH or lente insulin per kilogram of body weight given twice daily. Insulin resistance should be suspected if control of glycemia is poor despite an insulin dosage in excess of 1.5 U/kg, when excessive amounts of insulin (i.e., insulin dosage >1.5 U/kg) are necessary to maintain the blood glucose concentration below 300 mg/dl, and when control of glycemia is erratic and insulin requirements are constantly changing in an attempt to maintain control of glycemia. Failure of the blood glucose concentration to decrease below 300 mg/dl during a serial blood glucose curve is suggestive of, but not definitive for, the presence of insulin resistance. An insulin resistance–type blood glucose curve can also result from stress-induced hyperglycemia, the Somogyi response, and other problems with insulin therapy, and a decrease in the blood glucose concentration below 300 mg/dl can occur with disorders causing relatively mild insulin resistance. Serum fructosamine concentrations are typically greater than 500  $\mu$ mol/L in dogs with insulin resistance and can exceed 700  $\mu$ mol/L if resistance is severe.

Many disorders can interfere with insulin action (see Box 52-7). The most common in diabetic dogs include diabetogenic drugs (i.e., glucocorticoids), severe obesity, hyperadrenocorticism, diestrus, chronic pancreatitis, renal insufficiency, oral and urinary tract infections, hyperlipidemia, and insulin antibodies in dogs treated with beef insulin. Obtaining a complete history and performing a thorough physical examination is the most important step in identifying these concurrent disorders. If the history and physical examination are unremarkable, a CBC, serum biochemical analysis, serum pancreatic lipase immunoreactivity, serum progesterone concentration (intact female dog), abdominal ultrasound, and urinalysis with bacterial culture should be obtained to further screen for concurrent illness. Additional tests will be dependent on results of the initial screening tests (Box 52-8).

## CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Complications resulting from diabetes or its treatment are common in diabetic dogs and include blindness and anterior uveitis resulting from cataract formation, hypoglycemia, chronic pancreatitis, recurring infections, poor glycemic control, and ketoacidosis (see Box 52-5). Many clients are hesitant to treat their newly diagnosed diabetic dog because of knowledge regarding chronic complications experienced in human diabetics and concern that a similar fate awaits their pet. However, clients should be assured that the devastating effects of human diabetes (e.g., nephropathy, vasculopathy, coronary artery disease) require 10 to 20 years or longer to develop and therefore are uncommon in diabetic dogs.

### **Cataracts**

Cataract formation is the most common and one of the most important long-term complications of diabetes mellitus in the dog. A retrospective-cohort study on the development of cataracts in 132 diabetic dogs referred to a university referral hospital found cataract formation in 14% of dogs at the time diabetes was diagnosed and a time interval for 25%, 50%, 75%, and 80% of the study population to develop cataracts at 60, 170, 370, and 470 days, respectively (Beam et al., 1999). The pathogenesis of diabetic cataract formation is thought to be related to altered osmotic relationships in the lens induced by the accumulation of sorbitol and fructose, sugars that are potent hydrophilic agents and cause an influx of

BOX 52-8

Diagnostic Tests to Consider for the Evaluation of Insulin Resistance in Diabetic Dogs and Cats

Complete blood count, serum biochemistry panel, urinalysis Bacterial culture of the urine

Plasma lipase immunoreactivity (PLI) (pancreatitis)

Serum trypsin-like immunoreactivity (TLI) (exocrine pancreatic insufficiency)

Adrenocortical function tests

Urine cortisol:creatinine ratio (spontaneous hyperadrenocorticism)

Low-dose dexamethasone suppression test (spontaneous hyperadrenocorticism)

ACTH-stimulation test (iatrogenic hyperadrenocorticism) Thyroid function tests

Baseline serum total and free thyroxine (hypothyroidism and hyperthyroidism)

Endogenous thyroid-stimulating hormone (hypothyroidism)

Serum progesterone concentration (diestrus in intact female dog)

Fasting serum triglyceride concentration (hyperlipidemia)
Plasma growth hormone or serum insulin-like growth factor
I concentration (acromegaly)

Serum insulin concentration 24 hours after discontinuation of insulin therapy (insulin antibodies)

Abdominal ultrasonography (adrenomegaly, adrenal mass, pancreatitis, pancreatic mass)

Thoracic radiography (cardiomegaly, neoplasia)

Computed tomography or magnetic resonance imaging (pituitary mass)

water into the lens, leading to swelling and rupture of the lens fibers and the development of cataracts. Cataract formation is an irreversible process once it begins, and it can occur quite rapidly. Diabetic dogs that are poorly controlled and have problems with wide fluctuations in the blood glucose concentration seem especially at risk for rapid development of cataracts. Blindness may be eliminated by removing the abnormal lens. Vision is restored in approximately 75% to 80% of diabetic dogs that undergo cataract removal. Factors that affect the success of surgery include the degree of glycemic control preceding surgery, presence of retinal disease, and presence of lens-induced uveitis. Acquired retinal degeneration affecting vision is more of a concern in older diabetic dogs than is diabetic retinopathy. Fortunately, acquired retinal degeneration is unlikely in an older diabetic dog with vision immediately before cataract formation. If available, electroretinography should be performed before surgery to evaluate retinal function.

### **Lens-Induced Uveitis**

During embryogenesis the lens is formed within its own capsule, and its structural proteins are not exposed to the immune system. Therefore immune tolerance to the crystalline proteins does not develop. During cataract formation and reabsorption lens proteins are exposed to the local immune system, resulting in inflammation and uveitis. Uveitis that occurs in association with a reabsorbing, hypermature cataract may decrease the success of cataract surgery and must be controlled before surgery. The treatment of lens-induced uveitis focuses on decreasing the inflammation and preventing further intraocular damage. Topical ophthalmic corticosteroids are the most commonly used drug for the control of ocular inflammation. However, systemic absorption of topically applied corticosteroids may cause insulin resistance and interfere with glycemic control of the diabetic state, especially in toy and miniature breeds. An alternative is the topical administration of nonsteroidal antiinflammatory agents (e.g., 0.03% flurbiprofen) or cyclosporine.

## **Diabetic Neuropathy**

Although a common complication in the diabetic cat (see p. 795), diabetic neuropathy is infrequently recognized in the diabetic dog. Subclinical neuropathy is probably more common than is severe neuropathy resulting in clinical signs. Clinical signs consistent with diabetic neuropathy are most commonly recognized in dogs that have been diabetic for a long time (i.e., 5 years or longer). Clinical signs and physical examination findings include weakness, knuckling, abnormal gait, muscle atrophy, depressed limb reflexes, and deficits in postural reaction testing. Diabetic neuropathy in the dog is primarily a distal polyneuropathy, characterized by segmental demyelination and remyelination and axonal degeneration and regeneration. There is no specific treatment for diabetic neuropathy besides meticulous metabolic control of the diabetic state.

### **Diabetic Nephropathy**

Although diabetic nephropathy has occasionally been reported in the dog, its clinical recognition appears to be low. Histopathologic findings include membranous glomerulonephropathy, glomerular and tubular basement membrane thickening, an increase in the mesangial matrix material, the presence of subendothelial deposits, glomerular fibrosis, and glomerulosclerosis. The pathogenic mechanism of diabetic nephropathy is unknown. Clinical signs depend on the severity of glomerulosclerosis and the functional ability of the kidney to excrete metabolic wastes. Initially, diabetic nephropathy is manifested as proteinuria, primarily albuminuria. As glomerular changes progress, glomerular filtration becomes progressively impaired, resulting in the development of azotemia and eventually uremia. With severe fibrosis of the glomeruli, oliguric and then anuric renal failure develops. There is no specific treatment for diabetic nephropathy apart from meticulous metabolic control of the diabetic state, conservative medical management of the renal insufficiency, and control of systemic hypertension.

### **Systemic Hypertension**

Diabetes mellitus and hypertension commonly co-exist in dogs. Struble et al. (1998) found the prevalence of hyperten-

sion to be 46% in 50 insulin-treated diabetic dogs, in which hypertension was defined as systolic, diastolic, or mean blood pressure greater than 160, 100, and 120 mm Hg, respectively. The development of hypertension was associated with the duration of diabetes and an increased albumin: creatinine ratio in the urine. Diastolic and mean blood pressure were higher in dogs with longer duration of disease. A correlation between control of glycemia and blood pressure was not identified. Treatment for hypertension should be initiated if the systolic blood pressure is consistently greater than 160 mm Hg.

## **Prognosis**

The prognosis is dependent on the presence and reversibility of concurrent diseases, ease of regulation of the diabetic state with insulin, and client commitment toward treating the disease. The mean survival time in diabetic dogs is approximately 3 years from the time of diagnosis. This survival time is somewhat skewed because dogs are often 8 to 12 years old at the time of diagnosis and a relatively high mortality rate exists during the initial 6 months because of concurrent lifethreatening or uncontrollable disease (e.g., ketoacidosis, acute pancreatitis, renal failure). Diabetic dogs that survive the initial 6 months can easily maintain a good quality of life for longer than 5 years with proper care by the clients, timely evaluations by the veterinarian, and good client-veterinarian communication.

## DIABETES MELLITUS IN CATS

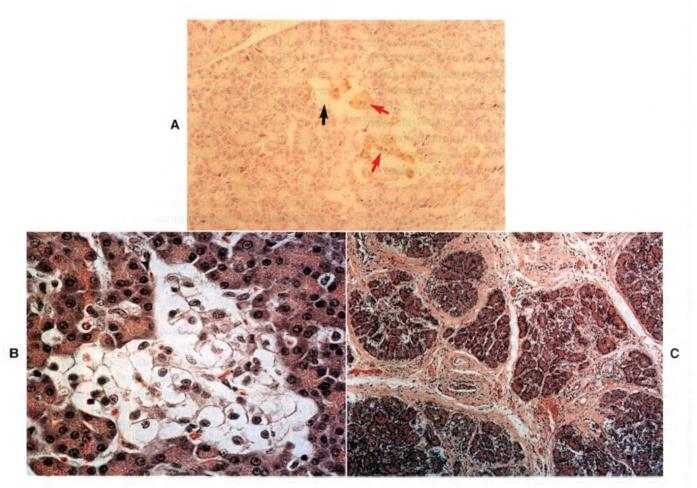

#### Etiology

Common histologic abnormalities in cats with diabetes mellitus include islet-specific amyloidosis,  $\beta$ -cell vacuolation and degeneration, and chronic pancreatitis. The cause of  $\beta$ -cell degeneration is not known. Other diabetic cats have a reduction in the number of pancreatic islets and/or insulincontaining  $\beta$  cells on immunohistochemical evaluation, suggesting additional mechanisms may be involved in the physiopathology of diabetes mellitus in cats. Although lymphocytic infiltration of islets, in conjunction with islet amyloidosis and vacuolation, has been described in diabetic cats, this histologic finding is very uncommon, and  $\beta$  cell and insulin autoantibodies have not been identified in newly diagnosed diabetic cats. The role of genetics remains to be determined.

Noninsulin-dependent type 2 diabetes may be identified in as many as 50% to 70% of newly diagnosed diabetic cats. Islet amyloidosis and insulin resistance are important factors in the development of noninsulin-dependent type 2 diabetes in cats. Islet-amyloid polypeptide (IAPP), or amylin, is the principal constituent of amyloid in adult cats with diabetes, is stored in  $\beta$ -cell secretory granules, and is co-secreted with insulin by the  $\beta$  cell. Stimulants of insulin secretion also stimulate the secretion of amylin. Chronic increased secretion of insulin and amylin, as occurs with obesity and other insulin-resistant states, results in aggregation and deposition

of amylin in the islets as amyloid (Fig. 52-12). IAPP-derived amyloid fibrils are cytotoxic and associated with apoptotic cell death of islet cells. If deposition of amyloid is progressive, as occurs with a sustained demand for insulin secretion in response to persistent insulin resistance, islet cell destruction progresses and eventually leads to diabetes mellitus. The severity of islet amyloidosis and  $\beta$  cell destruction determines, in part, whether the diabetic cat has IDDM or NIDDM. Total destruction of the islets results in IDDM and the need for insulin treatment for the rest of the cat's life. Partial destruction of the islets may or may not result in clinically evident diabetes, insulin treatment may or may not be required to control glycemia, and diabetes may or may not revert to a noninsulin-requiring state once treatment is initiated. If amyloid deposition is progressive, the cat will progress from subclinical diabetes to NIDDM and ultimately to IDDM. Current research regarding the etiopathogenesis of diabetes in the cat suggests that the difference between IDDM and NIDDM is primarily a difference in severity of loss of  $\beta$  cells and severity and reversibility of concurrent insulin resistance. Cats may have IDDM or NIDDM at the time diabetes is diagnosed, cats with NIDDM may progress to IDDM with time, cats with apparent IDDM may revert to a noninsulin requiring state after initiation of treatment, and cats may flip back and forth between IDDM and NIDDM as severity of insulin resistance and impairment of B cell function waxes and wanes.

Approximately 20% of diabetic cats become transiently diabetic, usually within 4 to 6 weeks after the diagnosis of diabetes has been established and treatment has been initiated. In these cats hyperglycemia, glycosuria, and clinical signs of diabetes resolve, and insulin treatment can be discontinued. Some diabetic cats may never require insulin treatment once the initial bout of clinical diabetes mellitus has dissipated, whereas others become permanently insulin dependent weeks to months after the resolution of a prior diabetic state. Studies suggest that cats with transient diabetes mellitus are in a subclinical diabetic state that becomes clinical when the pancreas is stressed by exposure to a concurrent insulin-antagonistic drug or disease, most notably glucocorticoids, megestrol acetate, and chronic pancreatitis (Fig. 52-13). Unlike healthy cats, those with transient diabetes mellitus have a reduced population of  $\beta$  cells, dysfunctional  $\beta$  cells, or both, which impairs the ability of the pancreas to compensate for concurrent insulin resistance. An inadequate insulin response results in hyperglycemia. Persistent hyperglycemia can, in turn, cause hypoinsulinemia by suppressing function of remaining  $\beta$  cells and can induce insulin resistance by promoting downregulation of glucose transport systems and causing a defect in posttransport insulin action. This phenomenon is referred to as glucose toxicity. B cells have an impaired response to stimulation by insulin secretagogues, thereby mimicking IDDM. The effects of glucose toxicity are potentially reversible upon correction of the hyperglycemic state. The clinician makes a correct diagnosis of diabetes mellitus, insulin and treatment of insulin-antagonistic disorders improve hyperglycemia and

#### FIG 52-12

**A,** Severe islet amyloidosis (straight arrow) in a cat with initial noninsulin-dependent diabetes mellitus (NIDDM) that progressed to insulin-dependent diabetes mellitus (IDDM). A pancreatic biopsy specimen was obtained while the animal was in the IDDM state. Residual B cells containing insulin (red arrows) are also present. (Immunoperoxidase stain,  $\times 100$ .) **B,** Severe vacuolar degeneration of islet cells. Pancreatic tissue was evaluated at necropsy 28 months after diabetes was diagnosed and 20 months after cat progressed from NIDDM to IDDM, requiring insulin to control blood glucose concentrations. The cat died from metastatic exocrine pancreatic adenocarcinoma. (H&E,  $\times 500$ .) **C,** Severe chronic pancreatitis with fibrosis in a diabetic cat with IDDM. The cat was euthanized because of persistent problems with lethargy, inappetence, and poorly controlled diabetes mellitus. (H&E,  $\times 100$ .) (**A** from Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

insulin resistance, glucose toxicity and  $\beta$  cell function improve, insulin secretion returns, and an apparent IDDM state resolves. The future requirement for insulin treatment depends on the underlying abnormality in the islets. If the abnormality is progressive (e.g., amyloidosis), eventually enough  $\beta$  cells will be destroyed and IDDM will develop.

#### **Clinical Features**

## **SIGNALMENT**

Although diabetes mellitus may be diagnosed in cats of any age, most diabetic cats are more than 9 years old (mean 10 years) at the time of diagnosis. Diabetes mellitus occurs predominantly in neutered male cats; no apparent breed predis-

position has been discovered, although Burmese cats may be overrepresented in Australia.

#### HISTORY

The history in virtually all diabetic cats includes polydipsia, polyuria, polyphagia, and weight loss. A common complaint of cat owners is the constant need to change the litter and an increase in the size of the litter clumps. Additional clinical signs include lethargy; decreased interaction with family members; lack of grooming behavior and development of a dry, lusterless, unkempt, or matted haircoat; and decreased jumping ability, rear limb weakness, or development of a plantigrade posture (Fig. 52-14). If the client does not notice clinical signs associated with uncomplicated diabetes, a dia-

Inflammation, infection, neoplasia, hormonal disorder or drug causes insulin antagonism

betic cat may be at risk for developing DKA (see p. 796). The time sequence from the onset of initial clinical signs to the development of DKA is unpredictable.

#### PHYSICAL EXAMINATION

Physical examination findings depend on the presence and severity of DKA and the nature of other concurrent disorders. The nonketotic diabetic cat has no classic physical examination findings. Many diabetic cats are obese but otherwise in good physical condition. Cats with prolonged untreated diabetes may have lost weight but are rarely emaciated unless concurrent disease (e.g., hyperthyroidism) is present. Newly diagnosed and poorly controlled diabetic cats often stop grooming and develop a dry, lusterless haircoat. Diabetes-induced hepatic lipidosis may cause hepatomegaly. Impaired ability to jump, weakness in the rear limbs, ataxia, or a plantigrade posture (i.e., the hocks touch the ground when the cat walks) may be evident if the cat has developed diabetic neuropathy. Distal muscles of the rear limbs may feel hard on digital palpation, and cats may object to palpation or manipulation of the rear limbs, presumably because of pain associated with the neuropathy. Additional abnor-

#### FIG 52-14

Note the palmigrade and plantigrade posture. The more severe and the more chronic the neuropathy, the less likely the neuropathy will improve after improvement in diabetic control.

malities may be identified in the ketoacidotic diabetic cat (see p. 796).

## **Diagnosis**

Establishing the diagnosis of diabetes mellitus is similar for cats and dogs and is based on identification of appropriate

clinical signs, persistent hyperglycemia, and glycosuria (see p. 769). Transient, stress-induced hyperglycemia is a common problem in cats and can cause the blood glucose concentration to increase above 300 mg/dl. Unfortunately, stress is a subjective state that cannot be accurately measured, is not always easily recognized, and may evoke inconsistent responses among individual cats. Glycosuria usually does not develop in cats with transient stress-induced hyperglycemia but can be present if stress is prolonged (i.e., hours). For this reason, presence of appropriate clinical signs, persistent hyperglycemia, and glycosuria should always be documented when establishing a diagnosis of diabetes mellitus in cats. If the clinician is in doubt, the stressed cat can be sent home with instructions for the client to monitor the urine glucose concentration with the cat in the nonstressed home environment. Alternatively, a serum fructosamine concentration can be measured (see p. 774). Documenting an increase in the serum fructosamine concentration supports the presence of sustained hyperglycemia; however, a serum fructosamine concentration in the upper range of normal can occur in symptomatic diabetic cats if the diabetes developed shortly before presentation of the cat to the veterinarian.

Clinical signs develop when hyperglycemia causes glycosuria and are the same regardless of the functional status of pancreatic islets. Information used to establish the diagnosis of diabetes mellitus does not provide information on the status of pancreatic islet health, presence of glucose toxicity, ability of the cat to secrete insulin, or the severity and reversibility of concurrent insulin resistance. Unfortunately, measurements of baseline serum insulin concentration or serum insulin concentrations after administration of an insulin secretagogue have not been consistent aids in differentiating IDDM and NIDDM in the cat. Identification of a baseline serum insulin concentration greater than 15 µU/ml (reference range, 5 to 20 µU/ml) in a newly diagnosed, untreated diabetic cat supports the presence of functional  $\beta$  cells and partial destruction of the islets; however, low or undetectable serum insulin concentrations do not rule out partial \( \beta \) cell loss because of the suppressive effects of glucose toxicity on circulating insulin concentrations.

A thorough evaluation of the cat's overall health is recommended once the diagnosis of diabetes mellitus has been established, for reasons discussed on p. 769. The minimal laboratory evaluation in any diabetic cat should include a CBC, serum biochemical panel, serum thyroxine concentration, and urinalysis with bacterial culture. If available, abdominal ultrasound should also be a routine part of the diagnostic evaluation because of the high prevalence of chronic pancreatitis in diabetic cats. Measurement of baseline serum insulin concentration or performance of an insulin secretory response test is not routinely done in cats because of problems encountered with glucose toxicity. Additional tests may be warranted after obtaining the history, performing the physical examination, or identifying ketoacidosis. See Box 52-4 for a list of potential clinical pathologic abnormalities.

#### **Treatment**

The significant incidence of NIDDM in cats raises interesting questions regarding the need for insulin treatment. Glycemic control can be maintained in some diabetic cats with dietary changes, oral hypoglycemic drugs, control of current diseases, discontinuation of insulin-antagonistic drugs, or a combination of these. The ultimate differentiation between IDDM and NIDDM is usually made retrospectively, after the clinician has had several weeks to assess the response of the cat to therapy and to determine the cat's need for insulin. The initial treatment strategy is based on the severity of clinical signs and physical abnormalities, presence or absence of ketoacidosis, general health of the cat, and client wishes. For most newly diagnosed diabetic cats, treatment includes insulin, adjustments in diet, and correction or control of concurrent insulin resistance.

## INITIAL INSULIN RECOMMENDATIONS FOR DIABETIC CATS

Diabetic cats are notoriously unpredictable in their response to exogenous insulin. No single type of insulin is routinely effective in maintaining control of glycemia, even with twicedaily administration. The initial insulin of choice ultimately is based on personal preferences and experiences. Commonly used insulin preparations for the long-term management of diabetic cats include human recombinant NPH, porcine lente, beef/pork PZI, and the insulin analog glargine (see the section on overview of insulin preparations, p. 769; see Fig. 52-11). All have potential problems in diabetic cats, primarily related to duration of insulin effect, not species of insulin and insulin antibody formation. Although lente and NPH insulin are consistently and rapidly absorbed after subcutaneous administration, the duration of effect of lente and especially NPH insulin can be considerably shorter than 12 hours, resulting in inadequate control of glycemia despite twice-daily administration (see Table 52-2). Although PZI is a longer-acting insulin, the timing of the glucose nadir is variable and occurs within 9 hours of PZI administration in the majority of treated diabetic cats. In one study PZI significantly improved control of glycemia in newly diagnosed diabetic cats and poorly controlled diabetic cats previously treated with ultralente or NPH insulin (Nelson et al., 2001). Comparison of efficacy between PZI and lente insulin has not been reported.

Insulin glargine is the longest-acting commercially available insulin for treatment of diabetes in humans and is currently a popular initial choice by veterinarians for the treatment of diabetes in cats. An unpublished study identified better glycemic control and a higher diabetes remission rate in newly diagnosed diabetic cats treated with glargine twice a day, compared with lente or PZI administered twice a day (Weaver and Rand, 2005). Another study found no difference in glycemic control in diabetic cats treated with glargine once a day versus diabetic cats treated with lente insulin twice a day, and a higher diabetes remission rate in diabetic cats treated with lente insulin (Weaver et al., 2006). In my experience, the duration of effect of glargine is quite

variable, with the glucose nadir occurring as soon as 4 hours and as late as 20 hours after administration. Glargine works well when given once or twice a day in some diabetic cats and does not work very well in others. Problems are usually related to duration of effect (i.e., too short or too long).

Currently, my personal preference for the initial treatment of newly diagnosed diabetes in cats is PZI at an initial dose of 1 U/cat. Because the majority of diabetic cats require PZI insulin twice a day, I prefer to start with twice-daily insulin therapy while the insulin dose is low to prevent problems with hypoglycemia and the Somoygi response. I switch to lente insulin given twice a day if problems with prolonged duration of PZI effect develop and glycemic control cannot be maintained with once-daily PZI, and I switch to glargine given twice a day if problems with short duration of PZI effect develop. When using glargine for the treatment of newly diagnosed diabetic cats, I use an initial dose of 1 unit/ cat administered once a day and switch to twice-daily therapy if subsequent blood glucose evaluations support a duration of effect of 12 hours or less. If PZI insulin becomes unavailable, I would use porcine lente insulin at an initial dose of 1 U/cat twice a day in the newly diagnosed diabetic cat.

#### DIET

The general principles for dietary therapy are listed in Box 52-6. Obesity, feeding practices, and content of the diet warrant discussion in diabetic cats. Obesity is common in diabetic cats and results from excessive caloric intake typically caused by free-choice feeding of dry cat food. Obesity causes reversible insulin resistance that resolves as obesity is corrected. Control of glycemia often improves, and some diabetic cats may revert to a subclinical diabetic state after weight reduction. Correction of obesity is difficult in cats because it requires restriction of daily caloric intake without a corresponding increase in caloric expenditure (i.e., exercise). Although there are several diets specifically formulated for weight reduction in cats, diets containing increased amounts of fiber and diets containing increased protein and decreased carbohydrate should be used in the obese diabetic cat for reasons discussed later. The reader is referred to Chapter 54 for more information on correction of obesity in cats.

The eating habits of cats vary considerably, from those cats that eat everything at the time it is offered to those that graze throughout the day and night. The primary goal of dietary therapy is to minimize the impact of a meal on post-prandial blood glucose concentrations. Consuming the same amount of calories in multiple small amounts throughout a 12-hour period should have less impact than consuming the calories at a single large meal. Half of the cat's total daily caloric intake should be offered at the time of each insulin injection and remain available to the cat to consume when it wishes. Attempts to force a grazing cat to eat the entire meal at one time usually fail and are not warranted as long as the cat has access to the food during the ensuing 12 hours. A similar approach is taken for diabetic dogs that are finicky eaters.

Cats are carnivores and, as such, have higher dietary protein requirements than omnivores such as humans and dogs. Hepatic glucokinase and hexokinase activity is lower in cats, compared with that for carnivores with omnivorous eating habits, and suggests that diabetic cats may be predisposed to developing higher postprandial blood glucose concentrations after consumption of diets containing a high carbohydrate load, and vice versa. Dietary studies in diabetic cats have documented improved control of glycemia with diets containing increased fiber content, increased protein and decreased carbohydrate content, and increased fat and decreased carbohydrate content plus treatment with the α-glucosidase inhibitor acarbose. The central theme in these dietary studies has been restriction of carbohydrate absorption by the gastrointestinal tract, either by inhibiting starch digestion (acarbose), inhibiting intestinal glucose absorption (fiber), or decreasing carbohydrate ingestion (low carbohydrate-containing diets). Intuitively, the most effective means to minimize gastrointestinal absorption of carbohydrates in the diabetic cat is to feed diets that contain minimal amounts of carbohydrate. Current recommendations include diets with high protein and low carbohydrate content and diets containing increased fiber and moderate carbohydrate content (see Box 52-6). Which diet will be most beneficial in improving control of glycemia in any given diabetic cat is unpredictable. The initial diet of choice is based on personal preference. Currently, I initially use diets containing high protein and low carbohydrate content, and if palatability, problems with renal insufficiency, or adverse effects become an issue or poor control of glycemia persists despite adjustments in insulin therapy, a switch to one of the fibercontaining diets should be considered. Diets containing high fat and low carbohydrate content (e.g., growth diets) are not recommended because of concerns related to the impact of high dietary fat content on obesity, hepatic lipidosis, chronic pancreatitis, and insulin resistance—the latter induced by increased circulating concentrations of nonesterified fatty acids,  $\beta$ -hydroxybutyric acid, and triglycerides.

## IDENTIFICATION AND CONTROL OF CONCURRENT PROBLEMS

Identification and correction of concurrent disorders that cause insulin resistance and interfere with the success of insulin therapy is critical to the successful treatment of diabetes in cats. Examples include obesity; chronic pancreatitis and other chronic inflammatory diseases; infection; and insulin-resistant disease such as hyperthyroidism, hyperadrenocorticism, and acromegaly. In diabetic cats with partial loss of  $\beta$  cells correction of insulin resistance may result in reversion from an insulin-dependent to a non-insulindependent or subclinical diabetic state. An evaluation of the diabetic cat for concurrent problems is indicated at the time diabetes is diagnosed and whenever control of glycemia deteriorates in a previously well-controlled cat and should include a thorough history, physical examination, CBC, serum biochemistry panel, serum thyroxine concentration, urinalysis with culture, and (if available) abdominal ultrasound.

### **ORAL HYPOGLYCEMIC DRUGS**

In the United States, five classes of oral hypoglycemic drugs are approved for the treatment of NIDDM in human beings: sulfonylureas, meglitinides, biguanides, thiazolidinediones, and α-glucosidase inhibitors. These drugs work by stimulating pancreatic insulin secretion (sulfonylureas, meglitinides), enhancing tissue sensitivity to insulin (biguanides, thiazolidinediones), or slowing postprandial intestinal glucose absorption (α-glucosidase inhibitors). Although controversial, chromium and vanadium are trace minerals that may also function as insulin sensitizers. Studies have documented the efficacy of sulfonylureas for treating diabetes in cats and α-glucosidase inhibitors for improving glycemic control in diabetic dogs. Insulin sensitizers as the sole therapeutic agent are of questionable benefit in diabetic dogs and cats because they require the presence of circulating insulin to be effective. Most diabetic cats subsequently shown to have NIDDM have low or nondetectable insulin concentrations at the time diabetes is diagnosed, in part because of the effects of concurrent glucose toxicity on circulating insulin concentrations.

### Sulfonylureas

Sulfonylurea drugs (e.g., glipizide, glyburide) are the most commonly used oral hypoglycemic drugs for the treatment of diabetes mellitus in cats. Sulfonylureas stimulate insulin secretion by pancreatic  $\beta$  cells. Some endogenous pancreatic insulin secretory capacity must exist for sulfonylureas to be effective. Clinical response to glipizide and glyburide treatment in diabetic cats has been variable, ranging from excellent (i.e., blood glucose concentrations decreasing to less than 200 mg/dl) to partial response (i.e., clinical improvement but failure to resolve hyperglycemia) to no response. Presumably, the population of functioning B cells varies from none (severe IDDM) to near normal (mild NIDDM) in treated cats, resulting in a response range from none to excellent. Cats with a partial response to glipizide have some functioning  $\beta$  cells but not enough to decrease the blood glucose concentration to less than 200 mg/dl. These cats may have severe NIDDM or the early stages of IDDM. Glipizide treatment has been found effective in improving clinical signs and severity of hyperglycemia in approximately 20% of diabetic cats.

No consistent parameters have been identified that allow the clinician to prospectively determine which cats will respond to glipizide or glyburide therapy. Identifying a high preprandial serum insulin concentration or an increase in serum insulin concentration during an insulin secretagogue test supports the diagnosis of NIDDM, but failure to identify these changes does not rule out the potential for a beneficial response to glipizide or glyburide. Selection of diabetic cats for treatment with glipizide must rely heavily on the veterinarian's assessment of the cat's health, severity of clinical signs, presence or absence of ketoacidosis, other diabetic complications (e.g., peripheral neuropathy), and the client's desires.

Glipizide (Glucotrol, Pfizer; 2.5 mg/cat administered q12h) and glyburide (Micronase, Pharmacia and Upjohn Company; 0.625 mg/cat q12h) are initially administered in conjunction with a meal to diabetic cats that are nonketotic and relatively healthy on physical examination (Fig. 52-15). Each cat is examined weekly during the first month of therapy. A history, complete physical examination, body weight, urine glucose/ ketone measurement, and blood glucose concentration are evaluated at each examination. If adverse reactions (Table 52-4) have not occurred after 2 weeks of treatment, the glipizide and glyburide dose is increased to 5.0 mg and 1.25 mg, respectively, q12h. Therapy is continued as long as the cat is stable. If euglycemia or hypoglycemia develops, the dose may be tapered down or discontinued and blood glucose concentrations reevaluated 1 week later to assess the need for the drug. If hyperglycemia recurs, the dose is increased or the sulfonylurea is reinitiated, with a reduction in dose in those cats previously developing hypoglycemia. Sulfonylurea treatment is discontinued and insulin therapy initiated if clinical signs continue to worsen, the cat becomes ill or develops ketoacidosis or peripheral neuropathy, blood glucose concentrations remain greater

**TABLE 52-4** 

Adverse Reactions to Glipizide Treatment in Diabetic Cats

ADVERSE REACTION	RECOMMENDATION
Vomiting within 1 hour of administration	Vomiting usually subsides after 2 to 5 days of glipizide therapy; decrease dose or frequency of administration if vomiting is severe; discontinue if vomiting persists >1 week
Increased serum hepatic enzyme activities	Continue treatment and monitor enzymes every 1 to 2 weeks initially; discontinue glipizide if cat becomes ill (lethargy, inappetence, vomiting) or the alanine transaminase activity exceeds 500 IU/L
Icterus	Discontinue glipizide treatment; reinstitute glipizide treatment at lower dose and frequency of administration once icterus resolves (usually within 2 weeks); discontinue treatment permanently if icterus recurs
Hypoglycemia	Discontinue glipizide treatment; recheck blood glucose concentration in 1 week; reinstitute glipizide therapy at lower dose or frequency of administration if hyperglycemia recurs

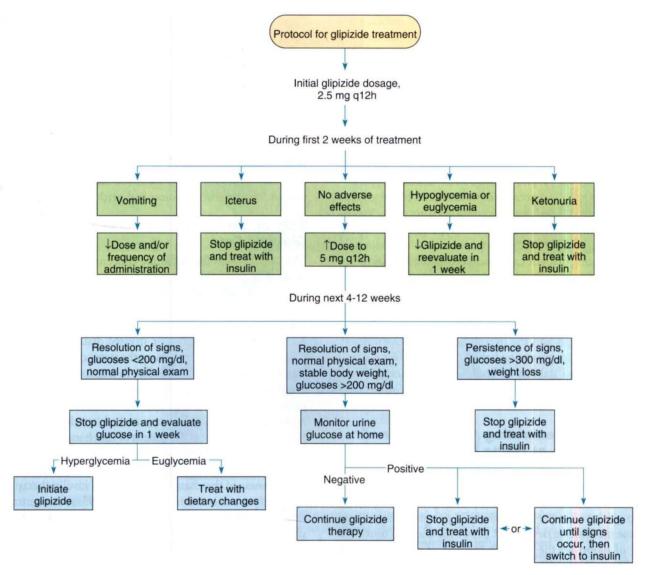

FIG 52-15
Algorithm for treating diabetic cats with the oral sulfonylurea drug, glipizide. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

than 300 mg/dl after 1 to 2 months of therapy, or the client becomes dissatisfied with the treatment. In some cats sulfonylureas become ineffective weeks to months later, and exogenous insulin is ultimately required to control the diabetic state. Presumably, the progression to IDDM coincides with progressive loss of  $\beta$  cells, a loss that may be exacerbated by sulfonylurea treatment. Regardless, the primary value of sulfonylureas is an alternative palatable option (pills versus injections) for clients initially unwilling to consider insulin injections and contemplating euthanasia of their cat. During the ensuing weeks many of these clients become willing to try insulin injections if sulfonylurea therapy fails.

#### Acarbose

Although the **u**-glucosidase inhibitor acarbose has been effective in improving glycemic control in diabetic dogs and

cats, the drug is not commonly used because of cost and adverse effects. Diarrhea and weight loss as a result of carbohydrate malassimilation occur in approximately 35% of treated dogs. Feeding carbohydrate-restricted diets is recommended in lieu of acarbose treatment in diabetic cats.

## IDENTIFYING INITIAL INSULIN REQUIREMENTS

The approaches to identifying insulin requirements in the newly diagnosed diabetic cat and dog are similar and discussed on p. 773. Most clients of diabetic cats are happy with the response to insulin treatment if the blood glucose concentrations range between 100 and 300 mg/dl throughout the day. Diabetic cats can have problems with hypoglycemia and the Somogyi response (see p. 780) at relatively small doses of insulin (1 to 2 U/injection). As such, the preference

is to have the client administer a fixed dose of insulin once control of glycemia is attained and discourage clients from adjusting the insulin dose at home without first consulting their veterinarian.

## **Techniques for Monitoring Diabetic Control**

The techniques for monitoring diabetic control are discussed on p. 774. One important factor that affects monitoring of diabetic cats is the propensity to develop stress-induced hyperglycemia caused by frequent visits to the veterinary hospital for blood samplings. Once stress-induced hyperglycemia develops, it is a perpetual problem and blood glucose measurements can no longer be considered accurate. Veterinarians must remain wary of stress hyperglycemia in diabetic cats and should take steps to prevent its development. Micromanaging diabetic cats is not recommended, and serial blood glucose curves should be done only when the clinician perceives a need to change insulin therapy. The determination of good versus poor control of glycemia should be based on the client's subjective opinion of the presence and severity of clinical signs and the overall health of the pet, ability of the cat to jump, grooming behavior, findings on physical examination, and stability of body weight. Generation of a serial blood glucose curve should be reserved for newly diagnosed and poorly controlled diabetic cats.

## Protocol for Generating the Serial Blood Glucose Curve at Home

An alternative to hospital-generated blood glucose curves is to have the client generate the blood glucose curve at home using the marginal ear vein prick technique in cats (the ear or lip prick technique in dogs) and a portable home blood glucose monitoring device that allows the client to touch the drop of blood on the ear with the end of the glucose test strip (Fig. 52-16). The marginal ear vein prick technique decreases the need for physical restraint during sample collection, thereby minimizing the cat's discomfort and stress. Accuracy of blood glucose results are similar when blood for glucose determination is obtained by ear prick and venipuncture. However, blood glucose results obtained by portable blood glucose monitoring devices may overestimate or, more commonly, underestimate the actual blood glucose values obtained with reference methods. This inherent error must be considered when interpreting blood glucose results obtained by a portable home blood glucose monitoring device. Several Web sites explain in detail the marginal ear vein prick technique in layman's terms and provide information on client experiences with the technique and with different portable home blood glucose meters. After diagnosing diabetes, the clinician should recommend a particular Web site and find out whether the client would be interested in monitoring blood glucose concentrations at home. The clinician should allow for ample time to teach the technique to clients who are willing to give it a try and provide advice regarding the proper way to perform a blood glucose curve (ideally, no more frequently than 1 day every 4 weeks) and how often to measure the blood glucose concentration on

the day of the curve (typically, at the time of insulin administration and 3, 6, 9, and 12 hours later). Use of the ear prick technique in cats has produced excellent results. Stress is often significantly reduced, and accuracy of the blood glucose measurements improved. Problems with the marginal ear vein prick technique include overzealous clients who start monitoring blood glucose concentrations too frequently, insulin overdosing and the Somogyi response caused by clients who interpret blood glucose results and adjust the insulin dose independent of input from the veterinarian, difficulty obtaining blood from the ear vein, and cats who do not tolerate manipulation and pricking of the ear.

## Role of Serum Fructosamine in Stressed Diabetic Cats

The use of serum fructosamine concentrations for assessing control of glycemia is discussed on p. 777. Serum fructosamine concentrations are not affected by acute transient increases in blood glucose concentration. Unlike blood glucose measurements, evaluation of serum fructosamine concentration in fractious or stressed diabetic cats provides reliable objective information on the status of glycemic control during the previous 2 to 3 weeks. In fractious or stressed cats the clinician must make an educated guess as to where the problem lies (e.g., wrong type of insulin, low insulin dose), make an adjustment in therapy, and rely on changes in serum fructosamine to assess the benefit of the change in treatment. Serum fructosamine concentrations can be measured before and 2 to 3 weeks after changing insulin therapy to assess the effectiveness of the change. If changes in insulin therapy are appropriate, a decrease in serum fructosamine concentration should occur. If the serum fructosamine concentration is the same or has increased, the change was ineffective in improving glycemic control, another change in therapy based on an educated guess should be done, and the serum fructosamine measured again 2 to 3 weeks later.

#### INSULIN THERAPY DURING SURGERY

The approaches to managing the diabetic cat and dog during surgery are similar and are discussed on p. 778.

#### COMPLICATIONS OF INSULIN THERAPY

Complications of insulin therapy are similar for diabetic dogs and cats and are discussed on p. 779. The most common complications of insulin therapy in the diabetic cat are recurring hypoglycemia; insulin overdose, which causes the Somogyi response; incorrect assessment of glycemic control caused by stress-induced hyperglycemia; short duration of effect of NPH; lente and, less commonly, PZI and glargine insulin; prolonged duration of effect of PZI and glargine insulin; and insulin resistance caused by concurrent inflammatory and hormonal disorders, most notably chronic pancreatitis.

## Stress Hyperglycemia

Transient hyperglycemia is a well-recognized problem in fractious, scared, or otherwise stressed cats. Hyperglycemia

#### FIG 52-16

Ear prick technique for measuring blood glucose concentration. **A,** A hot washcloth is applied to the pinna for 2 to 3 minutes to increase circulation to the ear. **B,** A spot is identified on the periphery of the outer side of the pinna, a small coating of petrolatum jelly is applied, and the spot is pricked with the lancet device supplied with the portable blood glucose meter. Gauze should be placed between the pinna and the digit holding the pinna to prevent pricking the finger if the blade of the lancet accidentally passes through the pinna. Petrolatum jelly is applied to help the blood form into a ball on the pinna as it seeps from the site that is lanced. **C,** Digital pressure is applied in the area of the lanced skin to promote bleeding. The glucose test strip is touched to the drop of capillary blood that forms and is removed once enough blood has been drawn into the test strip to activate the meter.

develops as a result of increased catecholamines and, in struggling cats, lactate concentrations. Blood glucose concentrations typically exceed 200 mg/dl in affected cats, and values in excess of 300 mg/dl are common. Stress hyperglycemia can significantly increase blood glucose concentrations in diabetic cats despite the administration of insulin, an effect that seriously compromises the clinician's ability to accurately judge the effectiveness of the insulin injection. Frequent hospitalizations and venipunctures for monitoring blood glucose concentrations are the most common cause of stress hyperglycemia. Blood glucose concentrations can remain greater than 400 mg/dl throughout the day despite administration of insulin. Failure to recognize the effect of stress on blood glucose results may lead to the erroneous perception that the diabetic cat is poorly controlled. Insulin

therapy is invariably adjusted, often by increasing the insulin dose, and another blood glucose curve recommended 1 to 2 weeks later. A vicious cycle ensues, which eventually culminates in the Somogyi response, clinically apparent hypoglycemia, or referral for evaluation of insulin resistance.

Failure to identify the presence of stress hyperglycemia and its impact on the interpretation of blood glucose measurements is one of the most important reasons that the status of glycemic control in diabetic cats is misinterpreted. Stress hyperglycemia should be suspected if the cat is visibly upset or aggressive or struggles during restraint and the venipuncture process. However, stress hyperglycemia can also be present in diabetic cats that are easily removed from the cage and do not resist the blood-sampling procedure. These cats are scared, but rather than become aggressive, they remain

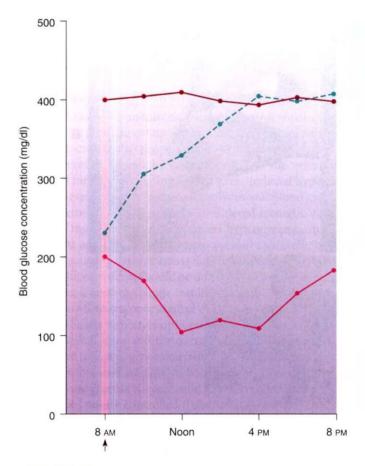

FIG 52-17

Blood glucose concentration curves in a 5.3-kg male cat receiving 2 U of recombinant human ultralente insulin (pink line) 2 weeks after the initiation of insulin therapy, 2 U of recombinant human ultralente insulin (blue line) 2 months later, and 6 U of recombinant human ultralente insulin Ired line) 4 months later. The insulin dose had been gradually increased on the basis of the blood glucose concentration curves. The client reported minimal clinical signs regardless of the insulin dose; at the 4-month recheck the cat had maintained its body weight and results of the physical exanination were normal. The cat became progressively more fractious during each hospitalization, supporting the existence of stress-induced hyperglycemia as the reason for the discrepancy between the blood glucose values and other parameters used to evaluate glycemic control. ↑, Subcutaneous insulin injection and food. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

crouched in the back of the cage, often have dilated pupils, and usually are flaccid when handled. Stress hyperglycemia should also be suspected if a disparity exists between assessment of glycemic control based on results of the history, physical examination, and stability of body weight; assessment of glycemic control based on results of blood glucose measurements; or when the initial blood glucose concentration measured in the morning is in an acceptable range (i.e., 150 to 250 mg/dl) but subsequent blood glucose concentrations increase steadily throughout the day (Fig. 52-17). Once stress hyperglycemia develops, it is a perpetual problem and

blood glucose measurements can no longer be considered accurate. If stress hyperglycemia is suspected, reliance on home monitoring of blood glucose or evaluation of sequential serum fructosamine concentrations (see p. 792) should be done, in addition to the history and physical examination findings.

## Hypoglycemia

Hypoglycemia, a common complication of insulin therapy, is discussed on p. 779. In diabetic cats symptomatic hypoglycemia is most apt to occur after sudden large increases in the insulin dose, after sudden improvement in concurrent insulin resistance, with excessive duration of insulin action in cats receiving insulin twice a day, after prolonged inappetence, and in insulin-treated cats that have reverted to a non-insulin-dependent state. In these situations severe hypoglycemia may occur before glucose counterregulation (i.e., secretion of glucagon, cortisol, epinephrine, growth hormone) is able to compensate for and reverse low blood glucose concentrations. The initial treatment approach for hypoglycemia is to discontinue insulin until hyperglycemia recurs and then reduce the ensuing insulin dose 25% to 50%. If hypoglycemia remains a reoccurring problem despite reductions in the insulin dose, excessive duration of insulin effect (see p. 781) or reversion to a noninsulin-dependent diabetic state should be considered. Reversion to a noninsulin-dependent diabetic state should be suspected if hypoglycemia remains a persistent problem despite administration of small doses of insulin (i.e., 1 U or less per injection) and administration of insulin once a day, if blood glucose concentrations are consistently below 150 mg/dl before insulin administration, if serum fructosamine concentration is less than 350 µmol/L, or if urine glucose test strips are consistently negative. Insulin therapy should be discontinued and periodic urine glucose testing should be performed in the home environment to identify recurrence of glycosuria.

## Insulin Overdosing and the Somogyi Response

Insulin overdosing and the Somogyi response is discussed on p. 780. A similar phenomenon, characterized by wide fluctuations in blood glucose concentration after which there are several days of persistent hyperglycemia, is recognized clinically in diabetic cats. However, the exact role of the counterregulatory hormones remains to be clarified. Insulin overdose that induces the Somogyi response is one of the most common causes of poor glycemic control in diabetic cats. It can be induced with insulin doses of 1 to 2 U per injection and can result in cats receiving 10 to 15 U of insulin per injection as veterinarians react to the persistence of clinical signs and increased blood glucose and serum fructosamine concentrations. A cyclic history of 1 or 2 days of good glycemic control after which there are several days of poor control should raise suspicion for insulin overdosing and the Somogyi response. Arbitrarily decreasing the insulin dose and evaluating the clinical response over the

ensuing 2 to 5 days is perhaps the best way to establish the diagnosis.

## Insulin Underdosing

Insulin underdosing is discussed on p. 780. Control of glycemia can be established in most diabetic cats using 1 U or less of insulin/kg of body weight administered twice each day. In general, insulin underdosing should be considered if the insulin dose is less than 1 U/kg/injection and the cat is receiving insulin twice a day. If insulin underdosing is suspected, the dose of insulin should be gradually increased by 0.5 to 1 U/injection per week. The effectiveness of the change in therapy should be evaluated by client perception of clinical response and measurement of serum fructosamine or serial blood glucose concentrations. Other causes for poor glycemic control should be ruled out before an increase in the insulin dose above 1 U/kg/injection is considered.

#### Short Duration of Insulin Effect

Short duration of insulin effect is discussed on p. 781. Short duration of insulin effect is a common problem in diabetic cats despite twice-daily insulin administration. Short duration of effect is most common with NPH and lente insulin (see Table 52-2). A diagnosis of short duration of insulin effect is made by demonstrating an initial blood glucose concentration greater than 300 mg/dl combined with a glucose nadir above 80 mg/dl that occurs less than 8 hours after insulin administration and recurrence of hyperglycemia (greater than 250 mg/dl) within 10 hours of the insulin injection (see Fig. 52-7). Treatment involves changing to a longeracting insulin preparation (i.e., PZI or glargine insulin).

## Prolonged Duration of Insulin Effect

Prolonged duration of insulin effect is discussed on p. 781. In diabetic cats problems with prolonged duration of insulin effect are most common with twice-daily administration of PZI and glargine insulin.

### Inadequate Insulin Absorption

Slow or inadequate absorption of subcutaneously deposited insulin was most commonly observed in diabetic cats receiving ultralente insulin, a long-acting basal insulin that had a slow onset and prolonged duration of effect. In affected cats the blood glucose concentration would decrease minimally, if at all, despite insulin doses of 8 to 12 U/cat. Ultralente insulin is no longer commercially available. A similar problem has not been reported for PZI or glargine insulin. Impaired and erratic absorption of insulin may occur as a result of thickening of the skin and inflammation of the subcutaneous tissues caused by chronic injection of insulin in the same area of the body. Rotation of the injection site helps prevent this problem.

## **Circulating Insulin-Binding Antibodies**

Insulin-binding antibodies are discussed on p. 782. Feline and beef insulin are similar, and feline, human, and porcine insulin differ. Fortunately, insulin antibody formation is not

common in diabetic cats treated with exogenous human insulin, despite differences between human and feline insulin. Studies identified an approximately equal frequency of positive serum insulin antibody titers in diabetic cats treated with beef insulin and recombinant human insulin. In my experience, antiinsulin antibody titers are weakly positive in most cats that develop insulin antibodies, prevalence of persistent titers is low, and presence of serum insulin antibodies do not appear to affect control of glycemia. Insulin resistance caused by insulin antibody formation appears to be uncommon. Switching from recombinant human or porcine source insulin to beef-/pork-source PZI may improve control of glycemia if insulin antibodies are the suspected cause for insulin ineffectiveness.

## Concurrent Disorders Causing Insulin Resistance

Concurrent disorders causing insulin resistance is discussed on p. 783. The most common concurrent disorders interfering with insulin effectiveness in cats include severe obesity, chronic inflammation such as chronic pancreatitis and gingivitis, renal insufficiency, hyperthyroidism, acromegaly, and hyperadrenocorticism (see Box 52-7). Obtaining a complete history and performing a thorough physical examination are the most important steps in identifying these concurrent disorders. If the history and physical examination are unremarkable, a CBC, serum biochemical analysis, serum thyroxine concentration, urinalysis with bacterial culture, and (if available) abdominal ultrasound should be obtained to further screen for concurrent illness. Additional tests will depend on the results of the initial screening tests (see Box 52-8).

## CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Chronic complications of diabetes mellitus are discussed on p. 783. The most common complications in the diabetic cat are hypoglycemia; chronic pancreatitis; weight loss; poor grooming behavior causing a dry, lusterless, and unkempt haircoat; and peripheral neuropathy of the hind limbs, causing weakness, inability to jump, a plantigrade stance, and ataxia (see Box 52-5). Diabetic cats are also at risk for ketoacidosis.

## **Diabetic Neuropathy**

Diabetic neuropathy is one of the most common chronic complications of diabetes in cats, with a prevalence of approximately 10%. Clinical signs of a co-existent neuropathy in the diabetic cat include weakness, impaired ability to jump, knuckling, a plantigrade posture with the cat's hocks touching the ground when it walks (see Fig. 52-14), muscle atrophy, depressed limb reflexes, and deficits in postural reaction testing. Clinical signs may progress to include the thoracic limbs (palmigrade posture; see Fig 52-14). Abnormalities on electrophysiologic testing are consistent with demyelination at all levels of the motor and sensory peripheral nerves and include decreased motor and sensory nerve

conduction velocities in pelvic and thoracic limbs and decreased muscle action potential amplitudes. Electromyographic abnormalities are usually absent and, when identified, are consistent with denervation. The most striking abnormality detected on histologic examination of nerve biopsies from affected cats is Schwann cell injury; axonal degeneration is identified in severely affected cats. The cause of diabetic neuropathy is not known. Currently, there is no specific therapy. Aggressive glucoregulation with insulin may improve nerve conduction and reverse the posterior weakness and plantigrade posture (see Fig. 52-14). However, the response to therapy is variable, and the risks of hypoglycemia increase with aggressive insulin treatment. Generally, the longer the neuropathy has been present and the more severe the neuropathy, the less likely it is that improving glycemic control will reverse the clinical signs of neuropathy.

### **Prognosis**

Diabetic cats and dogs have a similar prognosis (see p. 785). The mean survival time in diabetic cats is approximately 3 years from time of diagnosis. However, this survival time is skewed because cats are usually 8 to 12 years old at the time of diagnosis, and a high mortality rate exists during the first 6 months because of concurrent life-threatening or uncontrollable disease (e.g., ketoacidosis, pancreatitis, renal failure). Diabetic cats that survive the first 6 months can easily live longer than 5 years with the disease.

## DIABETIC KETOACIDOSIS

### Etiology

The etiopathogenesis of DKA is complex and usually affected by concurrent clinical disorders. Virtually all dogs and cats with DKA have a relative or absolute deficiency of insulin. DKA develops in some diabetic dogs and cats even though they receive daily injections of insulin, and their circulating insulin concentrations may even be increased. The "relative" insulin deficiency in these animals is created by concurrent insulin resistance, which in turn is created by concurrent disorders such as pancreatitis, infection, or renal insufficiency. Increased circulating concentrations of diabetogenic hormones, most notably glucagon, accentuate insulin deficiency by promoting insulin resistance; stimulate lipolysis, leading to ketogenesis; and stimulate hepatic gluconeogenesis, which worsens hyperglycemia.

Insulin deficiency and insulin resistance, together with increased circulating concentrations of diabetogenic hormones, play a critical role in the stimulation of ketogenesis. For the synthesis of ketone bodies (i.e., acetoacetic acid,  $\beta$ -hydroxybutyric acid, acetone) to be enhanced, there must be two major alterations in intermediary metabolism; (1) enhanced mobilization of free fatty acids (FFAs) from triglycerides stored in adipose tissue and (2) a shift in hepatic metabolism from fat synthesis to fat oxidation and ketogenesis. Insulin is a powerful inhibitor of lipolysis and FFA oxidation. A relative or absolute deficiency of insulin allows

lipolysis to increase, thus increasing the availability of FFAs to the liver and in turn promoting ketogenesis. As ketones continue to accumulate in the blood, the body's buffering system becomes overwhelmed and metabolic acidosis develops. As ketones accumulate in the extracellular space, the amount eventually surpasses the renal tubular threshold for complete resorption and they spill into the urine, contributing to the osmotic diuresis caused by glycosuria and enhancing the excretion of solutes (e.g., sodium, potassium, magnesium). Insulin deficiency per se also contributes to the excessive renal losses of water and electrolytes. The result is an excessive loss of electrolytes and water, leading to volume contraction, an underperfusion of tissues, and the development of prerenal azotemia. The rise in the blood glucose concentration raises plasma osmolality, and the resulting osmotic diuresis further aggravates the rise in plasma osmolality by causing water losses in excess of salt loss. The increase in plasma osmolality causes water to shift out of cells, leading to cellular dehydration. The metabolic consequences of DKA, which include severe acidosis, hyperosmolality, obligatory osmotic diuresis, dehydration, and electrolyte derangements, eventually become life threatening.

#### **Clinical Features**

DKA is a serious complication of diabetes mellitus that occurs most commonly in dogs and cats with diabetes that has gone undiagnosed. Less commonly, DKA develops in an insulin-treated diabetic dog or cat that is receiving an inadequate dose of insulin, often occurring in conjunction with an infectious, inflammatory, or insulin-resistant hormonal disorder. Because of the close association between DKA and newly diagnosed diabetes mellitus, the signalment of DKA in dogs and cats is similar to that of nonketotic diabetics.

The history and physical examination findings are variable, in part because of the progressive nature of the disorder and the variable time between the onset of DKA and client recognition of a problem. Polyuria, polydipsia, polyphagia, and weight loss develop initially but are either unnoticed or considered insignificant by the client. Systemic signs of illness (e.g., lethargy, anorexia, vomiting) ensue as ketonemia and metabolic acidosis develop and worsen, with the severity of these signs directly related to the severity of the metabolic acidosis and the nature of concurrent disorders that are often present. The time interval from the onset of the initial clinical signs of diabetes to the development of systemic signs of DKA is unpredictable and ranges from a few days to longer than 6 months. Once ketoacidosis begins to develop, however, severe illness usually becomes evident within 7 days.

Common physical examination findings include dehydration, lethargy, weakness, tachypnea, vomiting, and sometimes a strong odor of acetone on the breath. Slow, deep breathing may be observed in animals with severe metabolic acidosis. Gastrointestinal tract signs such as vomiting and abdominal pain are common in animals with DKA, in part because of the common concurrent occurrence of pancreatitis. Other intraabdominal disorders should also be con-

sidered and diagnostic tests (e.g., abdominal ultrasound) performed to help identify the cause of the gastrointestinal signs.

### Diagnosis

The diagnosis of diabetes mellitus is based on appropriate clinical signs, persistent fasting hyperglycemia, and glycosuria. Documenting ketonuria with reagent test strips that measure acetoacetic acid (KetoDiastix; Ames Division, Miles Laboratories) establishes the diagnosis of diabetic ketosis (DK), and documenting metabolic acidosis establishes the diagnosis of DKA. If ketonuria is not present but DKA is suspected, serum or urine can be tested for acetone using Acetest tablets (Ames Division, Miles Laboratories), serum can be tested for the presence of  $\beta$ -hydroxybutyrate using a benchtop chemistry analyzer, and plasma from heparinized hematocrit tubes can be used to test for the presence of acetoacetic acid using urine reagent strips used to document ketonuria, β-hydroxybutyrate and acetone are derived from acetoacetic acid, and commonly used urine reagent strips do not detect β-hydroxybutyrate and acetone. However, it is extremely uncommon for DKA to develop without an excess of acetoacetic acid.

## Treatment of "Healthy" Dogs or Cats with Diabetic Ketosis or Diabetic Ketoacidosis

If systemic signs of illness are absent or mild, serious abnormalities are not readily identifiable on physical examination, and metabolic acidosis is mild (i.e., total venous CO2 or arterial bicarbonate concentration greater than 16 mEq/L), short-acting regular crystalline insulin can be administered subcutaneously three times daily until the ketonuria resolves. Fluid therapy and intensive care are usually not needed. The insulin dose should be adjusted on the basis of blood glucose concentrations. To minimize hypoglycemia, the dog or cat should be fed one third of its daily caloric intake at the time of each insulin injection. The blood glucose and urine ketone concentrations, as well as the animal's clinical status, should be monitored. A decrease in the blood glucose concentration implies a decrease in ketone production. This, in combination with metabolism of ketones and loss of ketones in urine, will usually correct ketosis within 48 to 96 hours of initiating insulin therapy. Prolonged ketonuria is suggestive of a significant concurrent illness or inadequate blood insulin concentrations to suppress lipolysis and ketogenesis. Once the ketosis has resolved and the dog or cat is stable, eating, and drinking, insulin therapy may be initiated using longeracting insulin preparations (see pp. 765 and 788).

## Treatment of Sick Dogs or Cats with Diabetic Ketoacidosis

Aggressive therapy is called for if the dog or cat has systemic signs of illness (e.g., lethargy, anorexia, vomiting); physical examination reveals dehydration, depression, weakness, or a combination of these; or metabolic acidosis is severe (i.e., total venous CO<sub>2</sub> or arterial bicarbonate concentration less than 12 mEq/L). The five goals of treatment of a severely ill

ketoacidotic, diabetic pet are (1) to provide adequate amounts of insulin to suppress lipolysis, ketogenesis, and hepatic gluconeogenesis; (2) to restore water and electrolyte losses; (3) to correct acidosis; (4) to identify the factors precipitating the present illness; and (5) to provide a carbohydrate substrate (i.e., dextrose) when necessary to allow continued administration of insulin without causing hypoglycemia (Box 52-9). Proper therapy does not mean forcing a return to a normal state as rapidly as possible. Because osmotic and biochemical problems can arise as a result of overly aggressive therapy as well as from the disease itself, rapid changes in various vital parameters can be as harmful as, or more harmful than, no change. If all abnormal parameters can be slowly returned toward normal over a period of 24 to 48 hours, therapy is more likely to be successful.

Critically important information for formulating the initial treatment protocol include hematocrit and total plasma protein concentration; serum glucose, albumin, creatinine, and urea nitrogen concentrations; serum electrolytes; venous total CO<sub>2</sub> or arterial acid-base evaluation; and urine specific gravity. Abnormalities frequently associated with DKA are listed in Box 52-10. Once treatment for DKA is initiated, additional studies, such as a CBC, serum biochemistry panel, urinalysis, thoracic radiographs, and abdominal ultrasound, or diagnostic tests for pancreatitis, diestrus in the female dog, hyperthyroidism, and hyperadrenocorticism are usually warranted to identify underlying concurrent disorders (see Box 52-8).

#### **FLUID THERAPY**

Initiation of appropriate fluid therapy should be the first step in the treatment of DKA. Replacement of fluid deficiencies and maintenance of normal fluid balance are important to ensure adequate cardiac output, blood pressure, and blood flow to all tissues. Improvement of renal blood flow is especially critical. In addition to the general beneficial aspects of fluid therapy in any dehydrated animal, fluid therapy can correct the deficiency in total body sodium and potassium, dampen the potassium-lowering effect of insulin treatment, and lower the blood glucose concentration in diabetics, even in the absence of insulin administration. Unfortunately, fluid therapy alone does not suppress ketogenesis. For this reason, insulin is always required.

The type of parenteral fluid initially used will depend on the animal's electrolyte status, blood glucose concentration, and osmolality. Most dogs and cats with DKA have severe deficits in total body sodium, regardless of the measured serum concentration. Unless serum electrolyte concentrations dictate otherwise, the initial IV fluid of choice is 0.9% sodium chloride with appropriate potassium supplementation (see Table 55-1 and Table 55-2). Most dogs and cats with severe DKA usually are sodium depleted and therefore not suffering from dramatic hyperosmolality. Additional replacement crystalloid solutions that could be used if physiologic (0.9%) saline was not available include Ringer's solution, Ringer's lactated solution, Plasma-Lyte 148® (Baxter Healthcare Corporation), and Normosol-R (Abbott Laboratories).

BOX 52-9

### Initial Management of Dogs or Cats with Severe Diabetic Ketoacidosis

#### Fluid Therapy

Type: 0.9% saline

Rate: 60 to 100 ml/kg q24h initially; adjust based on hydration status, urine output, persistence of fluid losses

**Potassium supplement:** based on serum K<sup>+</sup> concentration (Table 55-1); if unknown, initially add KCl to provide 40 mEq of KCl per liter of fluids

**Phosphate supplement:** not indicated until serum phosphorus is less than 1.5 mg/dl, then 0.01 to 0.03 mmol phosphate/kg/hr in calcium-free intravenous fluids

**Dextrose supplement:** not indicated until blood glucose concentration is less than 250 mg/dl, then begin 5% dextrose infusion

#### **Bicarbonate Therapy**

Indication: administer if plasma bicarbonate concentration is less than 12 mEq/L or total venous CO<sub>2</sub> concentration is less than 12 mmol/L; if not known, do not administer unless animal is severely ill and then only once

**Amount:** mEq HCO<sub>3</sub><sup>-</sup> = body weight  $\{kg\} \times 0.4 \times (12 - animal's HCO<sub>3</sub><sup>-</sup>) \times 0.5$ ; if animal's HCO<sub>3</sub><sup>-</sup> or total CO<sub>2</sub> concentration is unknown, use 10 in place of  $\{12 - animal's HCO<sub>3</sub><sup>-</sup>\}$ 

Administration: add to intravenous fluids and give over 6 hours; do not give as bolus infusion

**Retreatment:** only if plasma bicarbonate concentration remains less than 12 mEq/L after 6 hours of therapy

#### Insulin Therapy

Type: regular crystalline insulin

#### **Administration Technique**

Intermittent intramuscular technique: initial dose, 0.2 U/kg intramuscularly; then 0.1 U/kg intramuscularly hourly until blood glucose concentration is less than 250 mg/dl; then switch to regular insulin administered subcutaneously q6-8h.

Low-dose intravenous infusion technique: to prepare infusion, add 2.2 U/kg (dogs) or 1.1 U/kg (cats) of regular insulin to 250 ml of 0.9% saline; run 50 ml through the drip set and discard; then administer via infusion or syringe pump through a line separate from that used for fluid therapy at an initial rate of 10 ml/hour; adjust infusion rate according to hourly blood glucose measurements; switch to subcutaneous regular insulin q6-8h once blood glucose is less than 250 mg/dl or continue insulin infusion at a decreased rate to prevent hypoglycemia until the insulin preparation is exchanged for a longer-acting product.

Goal: gradual decline in blood glucose concentration, preferably around 75 mg/dl/hour until concentration is less than 250 mg/dl

#### **Ancillary Therapy**

Concurrent pancreatitis is common in diabetic ketoacidosis; nothing by mouth and aggressive fluid therapy usually indicated

Concurrent infections are common in diabetic ketoacidosis; use of broad-spectrum, parenteral antibiotics usually indicated Additional therapy may be needed, depending on nature of concurrent disorders

#### **Patient Monitoring**

Blood glucose measurement q1-2h initially; adjust insulin therapy and begin dextrose infusion when decreases below 250 mg/dl

Hydration status, respiration, pulse q2-4h; adjust fluids accordingly

Serum electrolyte and total venous  $CO_2$  concentrations q6-12h; adjust fluid and bicarbonate therapy accordingly

Urine output, glycosuria, ketonuria q2-4h; adjust fluid therapy accordingly

Body weight, packed cell volume, temperature, and blood pressure daily

Additional monitoring, depending on concurrent disease

Hypotonic fluids (e.g., 0.45% saline) are rarely indicated in dogs and cats with DKA, even when severe hyperosmolality is present. Hypotonic fluids do not provide adequate amounts of sodium to correct the sodium deficiency, restore normal fluid balance, or stabilize blood pressure. Rapid administration of hypotonic fluids can also cause a rapid decrease in the osmolality of extracellular fluid (ECF), which may result in cerebral edema, deterioration in mentation, and eventually coma. Hyperosmolality is best treated with isotonic fluids and the judicious administration of insulin. Fluid administration should be directed at gradually replacing hydration deficits over 24 hours while also supplying maintenance fluid needs and matching ongoing losses. Rapid replacement of fluids is rarely indicated unless the dog or cat is in shock. Once the animal is out of this critical phase, fluid replacement should be decreased in an effort to correct the fluid imbalance in a slow but steady manner. As a general rule of thumb, a fluid rate of 1.5 to 2 times maintenance (i.e., 60 to 100 ml/kg q24h) is typically chosen initially, with subsequent adjustments based on frequent assessment of hydration status, urine output, severity of azotemia, and persistence of vomiting and diarrhea.

## **Potassium Supplementation**

Most dogs and cats with DKA initially have either normal or decreased serum potassium concentrations. During therapy for DKA the serum potassium concentration decreases because of rehydration (dilution), insulin-mediated cellular uptake of potassium (with glucose), continued urinary losses, and correction of acidemia (translocation of potassium into the intracellular fluid compartment; Fig. 52-18). Severe hypokalemia is the most common complication that devel-

ops during the initial 24 to 36 hours of treatment of DKA. Dogs and cats with hypokalemia require aggressive potassium replacement therapy to replace deficits and to prevent worsening, life-threatening hypokalemia after initiation of insulin therapy. The exception to potassium supplementation of fluids is hyperkalemia associated with oliguric renal failure. Potassium supplementation should initially be withheld in these dogs and cats until glomerular filtration is

BOX 52-10

Common Clinicopathologic Abnormalities Identified in Dogs and Cats with Diabetic Ketoacidosis

Neutrophilic leukocytosis, signs of toxicity if septic Hemoconcentration Hyperglycemia Hypercholesterolemia, lipemia Increased alkaline phosphatase activity Increased alanine aminotransferase activity Increased blood urea nitrogen and serum creatinine concentrations Hyponatremia Hypochloremia Hypokalemia Metabolic acidosis (decreased total carbon dioxide concentration) Hyperlipasemia Hyperamylasemia **Hyperosmolality** Glycosuria Ketonuria Urinary tract infection

restored, urine production increases, and hyperkalemia is resolving.

Ideally, the amount of potassium required should be based on actual measurement of the serum potassium concentration. If an accurate measurement of serum potassium is not available, 40 mEq of potassium should initially be added to each liter of intravenous fluids. Normal saline solution does not contain potassium, and Ringer's solution contains 4 mEq of potassium per liter; thus these fluids should be supplemented with 40 mEq and 36 mEq of potassium, respectively. Subsequent adjustments in potassium supplementation should be based on measurement of serum potassium, preferably every 6 to 8 hours until the dog or cat is stable and serum electrolytes are in the normal range.

## **Phosphate Supplementation**

Most dogs and cats with DKA have either normal or decreased serum phosphorus concentrations on pretreatment testing. Within 24 hours of initiating treatment for DKA, serum phosphorus concentration can decline to severe levels (i.e., <1 mg/dl) as a result of the dilutional effects of fluid therapy, the intracellular shift of phosphorus following the initiation of insulin therapy, and continuing renal and gastrointestinal loss (see Fig. 52-18). Hypophosphatemia affects primarily the hematologic and neuromuscular systems in dogs and cats. Hemolytic anemia is the most common problem and can be life threatening if not recognized and treated. Weakness, ataxia, and seizures may also be observed. Severe hypophosphatemia may be clinically silent in many animals

Phosphate therapy is indicated if clinical signs or hemolysis are identified or if the serum phosphorus concentration decreases to less than 1.5 mg/dl. Phosphate is supplemented

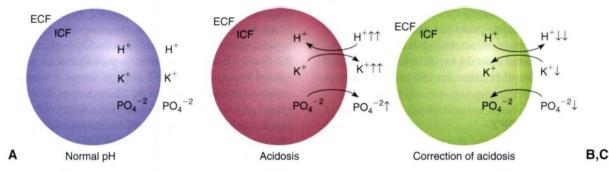

FIG 52-18

Redistribution of extracellular fluid (ECF) and intracellular fluid (ICF) hydrogen, potassium, and phosphate ions in response to a decrease in ECF pH (i.e., acidosis), an increase in ECF glucose and osmolality, and the translocation of water from the ICF to the ECF compartment and subsequent correction of acidosis and the intracellular shift of glucose and electrolytes with insulin treatment. **A,** Normal ECF pH. **B,** ECF H+ concentration increases during acidosis, causing H+ to move into cells and down its concentration gradient. Increase in ECF glucose and osmolality causes extracellular shift of water, K+, and  $PO_4^{+2}$ . **C,** ECF H+ concentration decreases during correction of acidosis, causing H+ to move out of cells. Insulin administration and correction of acidemia cause an intracellular shift of glucose, K+ and  $PO_4^{+2}$ , decreasing ECF K+ and  $PO_4^{+2}$  concentration. (Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004,WB Saunders.)

by IV infusion. Potassium and sodium phosphate solutions contain 3 mmol of phosphate and either 4.4 mEq of potassium or 4 mEq of sodium per milliliter. The recommended dosage for phosphate supplementation is 0.01 to 0.03 mmol of phosphate per kilogram of body weight per hour, preferably administered in calcium-free IV fluids (e.g., 0.9% sodium chloride). In dogs and cats with severe hypophosphatemia it may be necessary to increase the dosage to 0.03 to 0.12 mmol/kg/hour. Because the dose of phosphate necessary to replete an animal and the animal's response to therapy cannot be predicted, it is important to initially monitor the serum phosphorus concentration every 8 to 12 hours and adjust the phosphate infusion accordingly. Adverse effects from overzealous phosphate administration include iatrogenic hypocalcemia and its associated neuromuscular signs, hypernatremia, hypotension, and metastatic calcification. Serum total or (preferably) ionized calcium concentration should be measured at the same time as serum phosphorus concentration and the rate of phosphate infusion decreased if hypocalcemia is identified. Phosphorus supplementation is not indicated in dogs and cats with hypercalcemia, hyperphosphatemia, oliguria, or suspected tissue necrosis. If renal function is in question, phosphorus supplementation should not be done until the status of renal function and serum phosphorus concentration are known.

## **Magnesium Supplementation**

Plasma total and ionized magnesium concentrations may be within or below the reference range at the time DKA is diagnosed in the dog or cat, often decrease during the initial treatment of DKA, and typically normalize without treatment as the DKA resolves. Clinical signs of hypomagnesemia do not usually occur until the serum total and ionized magnesium concentration is less than 1.0 and 0.5 mg/dl, respectively, and even at these low levels many dogs and cats remain asymptomatic. I do not routinely treat hypomagnesemia in dogs or cats with DKA unless problems with persistent lethargy, anorexia, weakness, or refractory hypokalemia or hypocalcemia are encountered after 24 to 48 hours of fluid and insulin therapy and another cause for the problem cannot be identified (see p. 780).

## **Bicarbonate Therapy**

The clinical presentation of the dog or cat, in conjunction with the plasma bicarbonate or total venous  $CO_2$  concentration, should be used to determine the need for bicarbonate therapy. Bicarbonate supplementation is not recommended when plasma bicarbonate (or total venous  $CO_2$ ) is 12 mEq/L or greater, especially if the animal is alert. An alert dog or cat probably has a normal or near-normal pH in the cerebrospinal fluid (CSF). The acidosis in these animals is corrected through insulin and fluid therapy. Improvement in renal perfusion enhances urinary loss of ketoacids, and insulin therapy markedly diminishes the production of ketoacids. Acetoacetate and  $\beta$ -hydroxybutyrate are also metabolically usable anions, and 1 mEq of bicarbonate is generated from each 1 mEq of ketoacid metabolized.

When the plasma bicarbonate concentration is 11 mEq/L or less (total venous CO<sub>2</sub> is below 12), bicarbonate therapy should be initiated. Many of these animals have severe depression that may be a result of concurrent severe central nervous system acidosis. Metabolic acidosis should be corrected slowly, thereby avoiding major alterations in the pH of the CSF. Only a portion of the bicarbonate deficit is given initially over a 6-hour period. The bicarbonate deficit (i.e., the milliequivalents of bicarbonate initially needed to correct acidosis to the critical level of 12 mEq/L over a period of 6 hours) is calculated by the following formula:

### mEq bicarbonate = body weight (kg) $\times 0.4 \times (12 - \text{animal's})$ bicarbonate) $\times 0.5$

If the serum bicarbonate concentration is not known, the following formula should be used:

#### mEq bicarbonate = body weight (kg) $\times$ 2

The difference between the animal's serum bicarbonate concentration and the critical value of 12 mEq/L represents the treatable base deficit in DKA. If the animal's serum bicarbonate concentration is not known, the number 10 should be used for the treatable base deficit. The factor 0.4 corrects for the ECF space in which bicarbonate is distributed (40% of body weight). The factor 0.5 provides one half of the required dose of bicarbonate in the IV infusion. This technique allows a conservative dose to be given over a 6-hour period. Bicarbonate should never be given by bolus infusion. After 6 hours of therapy the acid-base status should be reevaluated and a new dose calculated. Once the plasma bicarbonate level is greater than 12 mEq/L, further bicarbonate supplementation is not indicated.

## INSULIN THERAPY

Insulin therapy is critical for the resolution of ketoacidosis. However, overzealous insulin treatment can cause severe hypokalemia, hypophosphatemia, and hypoglycemia during the first 24 hours of treatment—problems that can be minimized by appropriate fluid therapy, frequent monitoring of serum electrolytes and blood glucose concentrations, and modification of the initial insulin treatment protocol as indicated. Initiating appropriate fluid therapy should always be the first step in the treatment of DKA. Delaying insulin therapy for a minimum of 1 to 2 hours is recommended to allow the benefits of fluid therapy to begin to be realized before the glucose, potassium, and phosphorus-lowering effects of insulin therapy commence. Additional delays and decisions on the initial dosage of insulin administered are based on serum electrolyte results. If the serum potassium concentration is within the normal range after 2 hours of fluid therapy, insulin treatment should commence as described in the subsequent paragraphs. If hypokalemia persists, insulin therapy can be delayed an additional 1 to 2 hours to allow fluid therapy to replenish potassium, the initial insulin dose can be reduced to dampen the intracellular shift of potassium and phosphorus, or both can be

done. However, insulin therapy should be started within 4 hours of initiating fluid therapy.

The amount of insulin needed by an individual animal is difficult to predict. Therefore an insulin preparation with a rapid onset of action and a brief duration of effect is ideal for making rapid adjustments in the dose and frequency of administration to meet the needs of that particular dog or cat. Rapid-acting regular crystalline insulin meets these criteria and is recommended for the treatment of DKA.

Insulin protocols for the treatment of DKA include the hourly intramuscular technique, the continuous low-dose IV infusion technique, and the intermittent intramuscular then subcutaneous technique. All three routes (IV, intramuscular, subcutaneous) of insulin administration are effective in decreasing blood glucose and ketone concentrations. Successful management of DKA is *not* dependent on the route of insulin administration. Rather, it is dependent on proper treatment of each disorder associated with DKA.

## Intermittent Intramuscular Regimen

Dogs and cats with severe DKA should receive an initial regular crystalline insulin loading dose of 0.2 U/kg followed by 0.1 U/kg every hour thereafter. The insulin dose can be reduced by 25% to 50% for the first 2 to 3 injections if hypokalemia is a concern. The insulin should be administered into the muscles of the rear legs to ensure that the injections are penetrating muscle rather than fat or subcutaneous tissue. Diluting regular insulin 1:10 with sterile saline and using 0.3 ml U100 insulin syringes are helpful when small doses of insulin are required. The blood glucose concentration should be measured every hour using a point-of-care chemistry analyzer or portable blood glucose monitoring device and the insulin dosage adjusted accordingly. The goal of initial insulin therapy is to slowly lower the blood glucose concentration to the range of 200 to 250 mg/dl, preferably over a 6- to 10-hour period. An hourly decline of 50 mg/dl in the blood glucose concentration is ideal. This provides a steady moderate decline, with no major shifts in osmolality. A declining blood glucose concentration also ensures that lipolysis and the supply of FFAs for ketone production have been effectively turned off. Glucose concentrations, however, decrease much more rapidly than do ketone levels. In general, hyperglycemia is corrected within 12 hours, but ketosis may take 48 to 72 hours to resolve.

Once the initial hourly insulin therapy brings the blood glucose concentration near 250 mg/dl, hourly administration of regular insulin should be discontinued and regular insulin given every 4 to 6 hours intramuscularly or, if hydration status is good, every 6 to 8 hours subcutaneously. The initial dose is usually 0.1 to 0.3 U/kg, with subsequent adjustments based on blood glucose concentrations. In addition, at this point the IV infusion solution should have enough 50% dextrose added to create a 5% dextrose solution (100 ml of 50% dextrose added to each liter of fluids). The blood glucose concentration should be maintained between 150 and 300 mg/dl until the animal is stable and eating. Usually, a 5% dextrose solution is adequate in maintaining the desired

blood glucose concentration. If the blood glucose concentration dips below 150 mg/dl or rises above 300 mg/dl, the insulin dose can be lowered or raised accordingly. Dextrose helps minimize problems with hypoglycemia and allows insulin to be administered on schedule. Delaying the administration of insulin delays correction of the ketoacidotic state.

## Constant Low-Dose Insulin Infusion Technique

Constant IV infusion of regular crystalline insulin is also effective in decreasing blood glucose concentrations. To prepare the infusion, regular crystalline insulin (2.2 U/kg for dogs; 1.1 U/kg for cats) is added to 250 ml of 0.9% saline and initially administered at a rate of 10 ml/hour in a line separate from that used for fluid therapy. This provides an insulin infusion of 0.05 (cat) and 0.1 (dog) U/kg/hour, an infusion rate that has been shown to produce plasma insulin concentrations between 100 and 200  $\mu$ U/ml in dogs. Because insulin adheres to glass and plastic surfaces, approximately 50 ml of the insulin-containing fluid should be run through the drip set before it is administered to the animal. The rate of insulin infusion can be reduced for the initial 2 to 3 hours if hypokalemia is a concern. Two separate catheters are recommended for treatment: a peripheral catheter for insulin administration and a central catheter for fluid administration and blood sampling. An infusion or syringe pump should be used to ensure a constant rate of insulin infusion.

Adjustments in the infusion rate are based on hourly measurements of blood glucose concentration; an hourly decline of 50 mg/dl in the blood glucose concentration is ideal. Once the blood glucose concentration approaches 250 mg/dl, the insulin infusion can be discontinued and regular insulin given every 4 to 6 hours intramuscularly or every 6 to 8 hours subcutaneously, as discussed for the hourly intramuscular protocol. Alternatively, the insulin infusion can be continued (at a decreased rate to prevent hypoglycemia) until the insulin preparation is exchanged for a longeracting product. Dextrose should be added to the IV fluids once the blood glucose concentration approaches 250 mg/dl, as discussed in the section on hourly intramuscular insulin technique.

## Intermittent Intramuscular/ Subcutaneous Technique

The intermittent intramuscular followed by intermittent subcutaneous insulin technique is less labor intensive than the other techniques for insulin administration, but the decrease in blood glucose can be rapid and the risk of hypoglycemia is greater. The initial regular crystalline insulin dose is 0.25 U/kg, administered intramuscularly. Subsequent intramuscular injections are repeated every 4 hours. Usually, insulin is administered intramuscularly only once or twice. Once the animal is rehydrated, the insulin is administered subcutaneously rather than intramuscularly every 6 to 8 hours. Subcutaneous administration is not recommended

initially because of problems with insulin absorption from subcutaneous sites of deposition in a dehydrated dog or cat. The dosage of intramuscular or subcutaneous insulin is adjusted according to blood glucose concentrations, which initially should be measured hourly beginning with the first intramuscular injection. An hourly decline of 50 mg/dl in the blood glucose concentration is ideal. Subsequent insulin dosages should be decreased by 25% to 50% if this goal is exceeded. Dextrose should be added to the IV fluids once the blood glucose concentration approaches 250 mg/dl, as discussed in the section on hourly intramuscular insulin technique.

## **Initiating Longer-Acting Insulin**

Longer-acting insulin (e.g., NPH, lente, PZI) should not be administered until the dog or cat is stable; eating; maintaining fluid balance without any IV infusions; and no longer acidotic, azotemic, or electrolyte-deficient. The initial dose of the longer-acting insulin is similar to the regular insulin dose being used just before switching to the longer-acting insulin. Subsequent adjustments in the longer-acting insulin dose should be based on clinical response and measurement of blood glucose concentrations, as described on p. 775.

#### **CONCURRENT ILLNESS**

Therapy for DKA frequently involves the management of concurrent, often serious illness. Common concurrent illnesses in dogs and cats with DKA include bacterial infection; pancreatitis; congestive heart failure; renal failure; cholangiohepatitis; and insulin-antagonistic disorders, most notably hyperadrenocorticism, hyperthyroidism, and diestrus. It may be necessary in such animals to modify the therapy for DKA (e.g., fluid therapy in animals with concurrent heart failure) or implement additional therapy (e.g., antibiotics), depending on the nature of the concurrent illness. Insulin therapy, however, should never be delayed or discontinued. Resolution of ketoacidosis can be achieved only through insulin therapy. If nothing is to be given per os, insulin therapy should be continued and the blood glucose concentration maintained with IV dextrose infusions. If a concurrent insulin-antagonistic disease is present, it may be necessary to eliminate the disease while the animal is still ill to improve insulin effectiveness and resolve the ketoacidosis.

## COMPLICATIONS OF THERAPY FOR DIABETIC KETOACIDOSIS

Complications caused by therapy for DKA are common and include hypoglycemia, central nervous system signs secondary to cerebral edema, severe hypokalemia, severe hypernatremia and hyperchloremia, and hemolytic anemia resulting from hypophosphatemia. Complications usually result from overly aggressive treatment, inadequate monitoring of the animal's condition, and failure to reevaluate biochemical parameters in a timely manner. DKA is a complex disorder that is associated with a high mortality rate if improperly managed. To minimize the risk of therapeutic complications

and improve the chances of a successful response to therapy, all abnormal parameters should be slowly returned toward normal over a period of 24 to 48 hours, the physical and mental status of the animal must be evaluated frequently (at least three to four times daily), and biochemical parameters (e.g., blood glucose, serum electrolyte, blood gas values) must be evaluated in a timely fashion. During the initial 24 hours the blood glucose concentration should be measured every 1 to 2 hours and serum electrolyte and blood gas values measured every 6 to 8 hours, with modifications in fluid, insulin, and bicarbonate therapy made accordingly.

## **Prognosis**

DKA remains one of the most difficult metabolic therapeutic challenges in veterinary medicine. Despite all precautions and diligent therapy, a fatal outcome is sometimes inevitable. Approximately 30% of cats and dogs with severe DKA die or are euthanized during the initial hospitalization. Death is usually the result of a severe underlying illness (e.g., oliguric renal failure, necrotizing pancreatitis), severe metabolic acidosis (i.e., arterial blood pH less than 7), or complications that develop during therapy (e.g., cerebral edema, hypokalemia). Nevertheless, if logical therapy is implemented and animals are monitored carefully, a positive outcome is attainable.

## INSULIN-SECRETING BETA-CELL NEOPLASIA

## **Etiology**

Functional tumors arising from the  $\beta$  cells of the pancreatic islets are malignant tumors that secrete insulin independent of the typically suppressive effects of hypoglycemia.  $\beta$  cell tumors, however, are not completely autonomous and respond to provocative stimuli such as an increase in blood glucose by secreting insulin, often in excessive amounts. Immunohistochemical analysis of  $\beta$  cell tumors has revealed a high incidence of multihormonal production, including pancreatic polypeptide, somatostatin, glucagon, serotonin, and gastrin. However, insulin has been identified as the most common product demonstrated within the neoplastic cells, and clinical signs are primarily those that result from insulininduced hypoglycemia.

Insulin-secreting  $\beta$  cell tumors are uncommon in dogs and rare in cats. Virtually all  $\beta$  cell tumors in dogs are malignant, and most dogs have microscopic or grossly visible metastatic lesions at the time of surgery. The most common metastatic sites are the regional lymphatics and lymph nodes, liver, and peripancreatic mesentery. Pulmonary metastasis is uncommon and occurs late in the disease. In most dogs hypoglycemia recurs weeks to months after surgical excision of the tumor. The high prevalence of metastatic lesions at the time afflicted dogs are initially examined results, in part, from the typically protracted time it takes for clinical signs to develop and the interval between the time a client initially observes signs and seeks assistance from a veterinarian. Most

dogs are symptomatic for 1 to 6 months before being brought to a veterinarian.

#### **Clinical Features**

## SIGNALMENT OF TREATMENT

 $\beta$  cell tumors typically occur in middle-aged or older dogs. The median age at the time of diagnosis of a  $\beta$  cell tumor in 97 dogs in our series was 10 years with an age range of 3 to 14 years. No sex-related predilection is seen.  $\beta$  cell tumors are most commonly diagnosed in large breeds of dogs such as the German Shepherd Dog, Labrador Retriever, and Golden Retriever.  $\beta$  cell tumors have been reported in Siamese and mixed-breed cats older than 10 years of age.

## **CLINICAL SIGNS**

Clinical signs are caused by hypoglycemia and an increase in circulating catecholamine concentrations and include seizures, weakness, collapse, ataxia, muscle fasciculations, and bizarre behavior (Box 52-11). The severity of clinical signs depends on the duration and severity of hypoglycemia. Dogs with chronic hypoglycemia or with recurring episodes appear to tolerate low blood glucose concentrations (20 to 30 mg/ dl) for prolonged periods without clinical signs, and only small additional changes in the blood glucose concentration are then required to produce symptomatic episodes. Fasting, excitement, exercise, and eating may trigger the development of clinical signs. Because of the compensatory counterregulatory mechanisms that are designed to increase the blood glucose concentration when hypoglycemia develops, clinical signs tend to be episodic and are generally observed for only a few seconds to minutes. If these counterregulatory mechanisms are inadequate, seizures occur as the blood glucose concentration continues to decrease. Seizures are often selflimiting, lasting from 30 seconds to 5 minutes, and may stimulate further catecholamine secretion and the activation of other counterregulatory mechanisms that increase the blood glucose concentration above critical levels.

#### PHYSICAL EXAMINATION

Physical examination findings in animals with  $\beta$  cell tumors are surprisingly unremarkable; dogs are usually free of visible or palpable abnormalities. Weakness and lethargy are the most common findings and are identified in approximately 40% and 20% of our cases, respectively. Collapsing episodes and seizures may occur during the examination but are uncommon. Weight gain is evident in some dogs and is probably a result of the potent anabolic effects of insulin.

## **Peripheral Neuropathy**

Peripheral neuropathies have been observed in dogs with β cell tumors and may cause paraparesis to tetraparesis; facial paresis to paralysis; hyporeflexia to areflexia; hypotonia; and muscle atrophy of the appendicular, masticatory, and/or facial muscles. Sensory nerves may also be affected. Onset of clinical signs may be acute (i.e., days) or insidious (i.e., weeks to months). The pathogenesis of the polyneuropathy is not known. Proposed theories include metabolic derangements of the nerves induced by chronic and severe hypoglycemia or some other tumor-induced metabolic deficiency, an immune-mediated paraneoplastic syndrome resulting from shared antigens between tumor and nerves, or toxic factors produced by the tumor that deleteriously affect the nerves. Treatment is aimed at surgical removal of the  $\beta$  cell tumor. Prednisone therapy (initially 1 mg/kg q24h) may also improve clinical signs.

#### **CLINICAL PATHOLOGY**

Results of the CBC and urinalysis are usually normal. The only consistent abnormality identified in serum biochemistry profiles is hypoglycemia. The median initial blood glucose concentration in 97 of our dogs with a  $\beta$  cell tumor was 38 mg/dl, with a range of 15 to 78 mg/dl. Ninety percent of the dogs had a random blood glucose concentration less than 60 mg/dl. Dogs with  $\beta$  cell tumors occasionally have a blood glucose concentration of 60 to 80 mg/dl. Such a finding does not rule out hypoglycemia as a cause of episodic weakness or seizure activity. Fasting with hourly evaluations of the blood glucose concentration should be carried out in dogs with suspected hypoglycemia. The time required to induce hypoglycemia with fasting in dogs with a  $\beta$  cell tumor depends in part on the extent of disease at the time the dog is examined and ranges from a few hours to longer than 24 hours. The remainder of the serum biochemistry profile is usually normal. Hypoalbuminemia, hypophosphatemia, hypokalemia, and increased alkaline phosphatase and alanine aminotransferase activities may occur, but these findings are considered nonspecific and not helpful in arriving at a definite diagnosis. A correlation between increased liver enzyme activities and metastasis of  $\beta$  cell tumors to the liver has not been established.

#### Diagnosis

The diagnosis of a  $\beta$  cell tumor requires initial confirmation of hypoglycemia, followed by documentation of inappropriate insulin secretion and identification of a pancreatic mass

<sup>\*</sup>Common clinical signs.

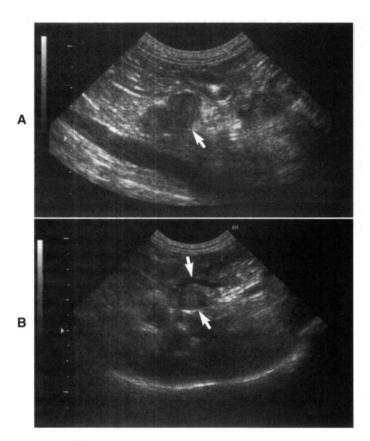

FIG 52-19
Ultrasonogram of the pancreas showing an islet β-cell tumor (arrow) (A) and an enlarged hepatic lymph node (arrows)
(B) resulting from metastasis of the β-cell tumor to the liver in a 9-year-old Cocker Spaniel.

using ultrasonography or laparotomy. Considering the potential differential diagnoses for hypoglycemia (see Box 52-2), a tentative diagnosis of a B cell tumor can often be made on the basis of the history, physical examination findings, and an absence of abnormalities other than hypoglycemia shown by routine blood tests. Abdominal ultrasonography can be used to identify a mass in the region of the pancreas and to look for evidence of potential metastatic disease in the liver and surrounding structures (Fig. 52-19). Because of the small size of most B cell tumors, abdominal ultrasonographic findings are often interpreted as normal, although a pancreatic mass or metastatic lesion can be found at surgery. A normal abdominal ultrasonographic finding does not rule out the diagnosis of a B cell tumor. Although computed tomographic imaging was better than ultrasonography or somatostatin receptor scintigraphy at identifying primary tumors, false-positive identification of metastatic sites was unacceptably high in one study (Robben et al., 2005). Thoracic radiographs are of minimal value in documenting metastatic disease, primarily because identifiable metastatic nodules in the lung occur late in the disease.

The diagnosis of a cell tumor is established by evaluating the serum insulin concentration at a time when hypoglycemia is present. Hypoglycemia suppresses insulin

secretion in normal animals, with the degree of suppression directly related to its severity. Hypoglycemia fails to have this same suppressive effect on insulin secretion if the insulin is synthesized and secreted from autonomous neoplastic cells because tumor cells that produce and secrete insulin are less responsive to hypoglycemia than are normal B cells. Invariably, the dog with a B cell tumor will have an inappropriate excess of insulin relative to that needed for a particular blood glucose concentration. Confidence in identifying an inappropriate excess of insulin depends on the severity of the hypoglycemia; the lower the blood glucose concentration, the more confident the clinician can be in identifying inappropriate hyperinsulinemia, especially when the serum insulin concentration falls in the normal range. If the blood glucose concentration is low and the insulin concentration is in the upper half of the normal range or increased, the animal has a relative or absolute excess of insulin that can best be explained by the presence of an insulin-secreting B cell tumor.

Most dogs with B cell neoplasia are persistently hypoglycemic. If the blood glucose concentration is less than 60 mg/ dl (preferably less than 50 mg/dl), serum should be submitted to a commercial veterinary endocrine laboratory for determination of glucose and insulin concentrations. If the blood glucose concentration is greater than 60 mg/dl, fasting may be necessary to induce hypoglycemia. Blood glucose concentrations should be evaluated hourly during the fast and blood obtained for glucose and insulin determination when the blood glucose concentration decreases to less than 50 mg/dl. It is important to remember that blood glucose results obtained from portable home blood glucosemonitoring devices are often lower than results obtained using benchtop methodologies. A blood sample for submission to a commercial laboratory for glucose and insulin determinations should not be obtained until the blood glucose measured on these devices is less than 40 mg/dl. Once hypoglycemia has been induced, the dog can be fed several small meals over the next 1 to 3 hours to prevent a marked increase in the blood glucose concentration and a potential postprandial reactive hypoglycemia.

Serum insulin concentrations must be evaluated simultaneously in relation to the blood glucose concentration. The serum insulin and glucose concentrations in the healthy fasted dog are usually between 5 and 20 U/ml and 70 and 110 mg/dl, respectively. Fnding a serum insulin concentration greater than 20 µU/ml in a dog with a corresponding blood glucose concentration less than 60 mg/dl (preferably less than 50 mg/dl) in combination with appropriate clinical signs and clinicopathologic findings strongly supports the diagnosis of a B cell tumor. A B cell tumor is also possible if the serum insulin concentration is in the high-normal range (10 to 20 µU/ml). Insulin values in the low-normal range (5 to 10 µU/ml) may be found in animals with other causes of hypoglycemia as well as a B cell tumor. Carefully reviewing the history, physical examination findings, and diagnostic tests results and, if necessary, repeating serum glucose and insulin measurements when hypoglycemia is

more severe will usually identify the cause of the hypoglycemia. Any serum insulin concentration that is below the normal range (typically less than 5  $\mu U/ml)$  is consistent with insulinopenia and does not indicate the presence of a  $\beta$  cell tumor. Similar guidelines are used for cats with a suspected  $\beta$  cell tumor.

#### **Treatment**

#### **OVERVIEW OF TREATMENT**

Treatment options for a B cell tumor include surgical exploration, medical treatment for chronic hypoglycemia, or both. Surgery offers a chance to cure dogs with a resectable solitary mass. In dogs with nonresectable tumors or with obvious metastatic lesions, removal of as much abnormal tissue as possible frequently results in remission, or at least alleviation, of clinical signs and an improved response to medical therapy. Survival time is longer in dogs undergoing surgical exploration and tumor debulking followed by medical therapy, compared with dogs that receive only medical treatment. Despite these benefits, surgery remains a relatively aggressive mode of treatment, in part because of the high prevalence of metastatic disease, the older age of many dogs at the time β cell neoplasia is diagnosed, and the potential for postoperative pancreatitis. As a general rule, I am less inclined to recommend surgery in aged dogs (i.e., 12 years and older), dogs with metastatic disease identified by ultrasonography, and dogs with significant concurrent disease. (See Suggested Readings for detailed information on surgical techniques.)

# PERIOPERATIVE MANAGEMENT OF DOGS UNDERGOING SURGERY

Until surgery is performed, the dog or cat with a  $\beta$  cell tumor must be protected from episodes of severe hypoglycemia. This can usually be accomplished through the frequent feeding of small meals and administration of glucocorticoids (Box 52-12). The IV administration of a balanced electrolyte solution containing 2.5% to 5% dextrose is important during the perioperative period. The goal of the dextrose infusion is to prevent clinical signs of hypoglycemia and maintain the blood glucose concentration at greater than 35 mg/dl, not to reestablish a normal blood glucose concentration.

If the dextrose infusion is ineffective in preventing severe hypoglycemia, a constant rate infusion of glucagon should be considered. Glucagon is a potent stimulant of hepatic gluconeogenesis and is effective in maintaining normal blood glucose concentrations in dogs with  $\beta$  cell neoplasia when administered by constant-rate infusion. Lyophilized glucagon USP (1 mg) is reconstituted with the diluent provided by the manufacturer (Eli Lilly), and the solution is added to 1 L of 0.9% saline, making a 1 µg/ml solution that can be administered by syringe pump. The initial dose is 5 to 10 ng/kg of body weight/minute. The dose is adjusted, as needed, to maintain the blood glucose concentration within the normal range. When discontinuing glucagon, the dose should be gradually decreased over 1 to 2 days.

Long-term Medical Therapy for Dogs with β-Cell Neoplasia

#### **Standard Treatments**

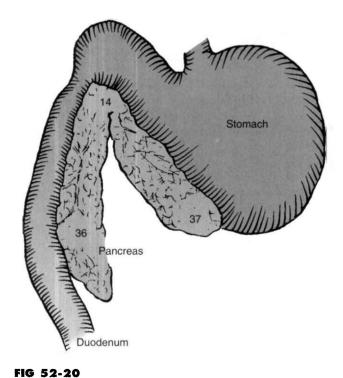

- 1. Dietary therapy
  - Feed canned or dry food in three to six small meals daily
  - Avoid foods containing monosaccharides, disaccharides, propylene glycol and corn syrup
- 2. Limit exercise
- 3. Glucocorticoid therapy
  - a. Prednisone, 0.5 mg/kg divided into two doses initially
  - Gradually increase dose and frequency of administration, as needed
  - c. Goal is to control clinical signs, not to reestablish euglycemia
  - d. Consider alternative treatments if signs of iatrogenic hypercortisolism become severe or glucocorticoids become ineffective

#### **Additional Treatments**

- 1. Diazoxide therapy
  - a. Continue standard treatment; reduce glucocorticoid dose to minimize adverse signs
  - b. Diazoxide, 5 mg/kg q12h initially
  - Gradually increase dose as needed, not to exceed 60 mg/kg/day
  - d. Goal is to control clinical signs, not to reestablish euglycemia
- 2. Somatostatin therapy
  - a. Continue standard treatment; reduce glucocorticoid dose to minimize adverse signs
  - b. Octreotide (Novartis Pharmaceuticals), 10 to 40 μg/ dog administered subcutaneously q12h to q8h
- 3. Streptozotocin therapy
  - a. Continue standard treatment; reduce glucocorticoid dose to minimize adverse signs
  - b. 0.9% saline diuresis for 3 hours, then streptozotocin, 500 mg/m², in 0.9% saline and administered intravenously over 2 hours, then 0.9% saline diuresis for 2 additional hours
  - c. Administer antiemetics immediately after streptozotocin administration to minimize vomiting
  - Repeat treatment every 3 weeks until hypoglycemia resolves or adverse reactions develop (e.g., pancreatitis, renal failure)

#### **POSTOPERATIVE COMPLICATIONS**

The most common postoperative complications are pancreatitis, hyperglycemia, and hypoglycemia. The development of these complications is directly related to the expertise of the surgeon, the location of the tumor in the pancreas (i.e., peripheral lobe versus central region; Fig. 52-20), the presence or absence of functional metastatic lesions, and the adequacy of fluid therapy during the perioperative period.

Tumor location in 87 dogs with islet B-cell tumors. (Adapted from Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB

Saunders.)

Severe pancreatitis occurs most commonly with attempts to remove tumors located in the central region of the pancreas, where the blood supply and pancreatic ducts are located. Tumors located in the central region of the pancreas should be considered inoperable because of the high prevalence of postoperative life-threatening pancreatitis despite appropriate treatment aimed at preventing its development, including aggressive fluid therapy, nothing by mouth for up to 72 hours after surgery, and appropriate dietary therapy during the ensuing week. The reader is referred to Chapter 40 for information on the treatment of pancreatitis.

The development of transient diabetes mellitus after surgical removal of a B cell tumor is not an indication of cure. It is believed to result from inadequate insulin secretion by atrophied normal B cells. Removal of all, or most, of the neoplastic cells acutely deprives the animal of insulin. Until the atrophied normal cells regain their secretory abilities, the animal will be hypoinsulinemic and may require exogenous insulin injections to maintain euglycemia. Insulin therapy is initiated postoperatively only if hyperglycemia and glycosuria persist for longer than 2 or 3 days beyond the time that all dextrose-containing IV fluids have been discontinued. Initial insulin therapy should be conservative—that is, 0.25 U of NPH or lente insulin per kilogram of body weight given once daily. Subsequent adjustments in insulin therapy should be made according to clinical response and blood glucose determinations (see p. 774). The need for insulin treatment is usually transient, lasting from a few days to several months.

Rarely, a dog will remain diabetic for more than a year. Client evaluation of the pet's urine glucose level is helpful in identifying when insulin therapy is no longer needed. Failure to identify glucose in the urine in conjunction with the disappearance of polyuria and polydipsia is an indication to discontinue insulin therapy. If hyperglycemia and glycosuria recur, insulin therapy can be reinstituted but at a lower dose.

Dogs that remain hypoglycemic after surgical removal of a  $\beta$  cell tumor have functional metastatic lesions. The dextrose and/or glucagon infusion should be continued postoperatively until pancreatitis has resolved (if present); the dog is stable, eating, and drinking; and medical treatment for chronic hypoglycemia can be initiated (see Box 52-12).

# MEDICAL TREATMENT FOR CHRONIC HYPOGLYCEMIA

Medical treatment for chronic hypoglycemia should be initiated if surgery is not performed or when clinical signs of hypoglycemia recur following surgery. The goals of medical treatment are to reduce the frequency and severity of clinical signs of hypoglycemia and prevent an acute hypoglycemic crisis, not to establish euglycemia, per se. Medical treatment is palliative and minimizes hypoglycemia by increasing the absorption of glucose from the intestinal tract (frequent feedings); increasing hepatic gluconeogenesis and glycogenolysis (glucocorticoids); or inhibiting the synthesis, secretion, or peripheral cellular actions of insulin (glucocorticoids, diazoxide, somatostatin; see Box 52-12).

#### **Frequent Feedings**

Frequent feedings provide a constant source of calories as a substrate for the excess insulin secreted by  $\beta$  cell tumors. Diets that are high in fat, complex carbohydrates, and fiber will delay gastric emptying and slow intestinal glucose absorption, helping to minimize the postprandial increase in the portal blood glucose concentration and the stimulation of insulin secretion by the tumor. Simple sugars are rapidly absorbed, have a potent stimulatory effect on insulin secretion by neoplastic  $\beta$  cells, and should be avoided. A combination of canned and dry dog food, fed in three to six small meals daily, is recommended. Daily caloric intake should be controlled because hyperinsulinemia promotes obesity. Exercise should be limited to short walks on a leash.

# **Glucocorticoid Therapy**

Glucocorticoid therapy should be initiated when dietary manipulations are no longer effective in preventing clinical signs of hypoglycemia. Glucocorticoids antagonize the effects of insulin at the cellular level, stimulate hepatic glycogenolysis, and indirectly provide the necessary substrates for hepatic gluconeogenesis. Prednisone is most often used at an initial dose of 0.25 mg/kg q12h. Adjustments in the dose are based on clinical response. The dose of prednisone required to control clinical signs increases with time in response to growth of the tumor and its metastatic sites. Eventually, the adverse effects of prednisone, specifically polyuria and poly-

dipsia, become unacceptable to clients. When this occurs, the dose of prednisone should be reduced but not stopped and additional therapy considered.

# Diazoxide Therapy

Diazoxide (Proglycem; Baker Norton Pharmaceuticals) is a benzothiadiazide diuretic that inhibits insulin secretion, stimulates hepatic gluconeogenesis and glycogenolysis, and inhibits tissue use of glucose. The net effect is hyperglycemia. Unfortunately, diazoxide is difficult to procure and is expensive. The initial dose is 5 mg/kg q12h. The dose is adjusted according to clinical response but should not exceed 60 mg/kg/day. The most common adverse reactions to diazoxide are anorexia and vomiting. Administering the drug with a meal or decreasing the dose, at least temporarily, is usually effective in controlling adverse gastrointestinal signs.

# Somatostatin Therapy

Octreotide (Sandostatin; Novartis Pharmaceuticals) is an analog of somatostatin that inhibits the synthesis and secretion of insulin by normal and neoplastic  $\beta$  cells. The responsiveness of  $\beta$  cell tumors to the suppressive effects of octreotide depends on the presence of membrane receptors for somatostatin on the tumor cells. Octreotide at a dose of 10 to 40  $\mu g/dog$ , administered subcutaneously two to three times a day, has alleviated hypoglycemia in approximately 40% to 50% of treated dogs. Adverse reactions have not been seen at these doses. Octreotide is not a viable option for most clients because of cost.

#### Streptozotocin Therapy

Streptozotocin is a naturally occurring nitrosourea that selectively destroys pancreatic  $\beta$  cells. The treatment protocol for  $\beta$  cell tumors in dogs involves a 0.9% saline diuresis for 7 hours with streptozotocin (500 mg/m<sup>2</sup>) administered over a 2-hour period beginning 3 hours after initiating the diuresis. Antiemetics are administered immediately after streptozotocin administration to minimize vomiting. Streptozotocin treatment is repeated every 3 weeks. The effectiveness of streptozotocin in improving hypoglycemia, controlling clinical signs, and prolonging survival time has been variable. Adverse reactions of streptozotocin treatment include vomiting, pancreatitis, diabetes mellitus, and renal failure. Renal failure is less likely when the drug is administered during fluid diuresis as described previously. (See Moore et al. [2002] in Suggested Readings for more information on the use of streptozotocin in treating β cell neoplasia in dogs.)

#### **Prognosis**

The long-term prognosis for  $\beta$  cell neoplasia is guarded to poor. Survival time is dependent, in part, on the willingness of the client to treat the disease. Tobin et al. (1999) reported a median survival time after diagnosis of only 74 days (range 8 to 508 days) in dogs treated medically, compared with 381 days (range 20 to 1758 days) in dogs that initially underwent surgery at a tertiary care center. The short survival time for

dogs treated medically was because many clients opted for euthanasia when seizures recurred or signs of iatrogenic hyperadrenocorticism developed. The extent to which surgery can alter the prognosis depends on the clinical stage of the disease, most notably the extent of metastatic lesions. Approximately 10% to 15% of dogs undergoing surgery for a  $\beta$  cell tumor die or are euthanized at the time of or within 1 month of surgery because of metastatic disease causing postoperative hypoglycemia that is refractory to medical management or because of complications related to pancreatitis. An additional 20% to 25% of dogs die or are euthanized within 6 months of surgery because of recurrence of clinical hypoglycemia that is refractory to medical management. The remaining 60% to 70% live beyond 6 months postoperatively, many beyond I year after surgery, before uncontrollable hypoglycemia develops, resulting in death or necessitating euthanasia. Additional surgery to debulk metastatic lesions may improve the animal's responsiveness to medical therapy and prolong the survival time in some dogs that become nonresponsive to medical treatment after the initial surgery.

# **GASTRIN-SECRETING NEOPLASIA**

Gastrin-secreting tumors (gastrinomas) are functional malignant tumors usually located in the pancreas of dogs and cats. Sites of metastasis include the liver, regional lymph nodes, spleen, and mesentery. Clinical signs result from the consequences of excess gastric hydrochloric acid secretion in response to excess secretion of gastrin by the tumor.

#### **Clinical Features**

The most consistent clinical signs are chronic vomiting, weight loss, anorexia, and diarrhea in an older animal (Box 52-13). Gastric and duodenal ulcers and esophagitis are common and may cause hematemesis, hematochezia, melena, and regurgitation. Acidification of intestinal contents may inactivate pancreatic digestive enzymes, precipitate bile salts,

interfere with formation of chylomicrons, and damage intestinal mucosal cells. Diarrhea with malabsorption and steatorrhea may develop as a consequence. Findings on physical examination include lethargy, fever, dehydration, abdominal pain, and shock if blood loss is severe or ulcers have perforated. Potential abnormalities identified on a CBC include a regenerative anemia, hypoproteinemia, and neutrophilic leukocytosis. Abnormalities in the serum biochemistry panel include hypoproteinemia, hypoalbuminemia, hypocalcemia, and mild increases in serum alanine aminotransferase and alkaline phosphatase activities. Hyponatremia, hypochloremia, hypokalemia, and metabolic alkalosis may develop in dogs and cats that vomit frequently. Hyperglycemia and hypoglycemia have been noted in a few cases. The urinalysis is usually unremarkable.

Abdominal radiographs are usually normal. If an ulcer has perforated through the serosal surface, radiographic signs consistent with peritonitis may be present. Contrastenhanced radiographic studies may show gastric or duodenal ulcers; thickening of the gastric rugal folds, pyloric antrum, or intestine; and the rapid intestinal transit of barium. In an animal with concurrent severe esophagitis, secondary megaesophagus or aberrant, nonperistaltic esophageal motility may be identified fluoroscopically. Ultrasonographic evaluation of the abdomen may identify a pancreatic mass or its metastasis. However, gastrinomas vary tremendously in size and may not be detected with ultrasound.

Gastroduodenoscopy may reveal severe esophagitis and ulceration, especially near the cardia. Gastric rugal folds may be thickened. Gastric and duodenal hyperemia, erosions, or ulcerations are often visible. Histologic evaluation of esophageal, gastric, and duodenal biopsy specimens may be normal or may reveal variable degrees of inflammation consisting of infiltrates of lymphocytes, plasma cells and neutrophils, gastric mucosal hypertrophy, fibrosis, and loss of the mucosal barrier.

# **Diagnosis**

Gastrinoma should be included among the differential diagnoses for any dog or cat with melena or hematemesis or in which severe gastric and duodenal ulceration is identified. Unless a pancreatic mass is identified by ultrasonography, most dogs and cats with gastrinoma will inadvertently be diagnosed with severe inflammatory bowel disease, gastroduodenal erosions, and ulcers, and they will be treated with inhibitors of gastric acid secretion, mucosal protectants, antibiotics, and changes in diet. The probability of a gastrinoma increases if ultrasonography reveals a pancreatic mass, the dog or cat does not respond to medical therapy directed at nonspecific inflammation and ulceration of the gastrointestinal tract, or clinical signs and gastrointestinal tract ulceration recur after antiulcer therapy is discontinued. A definitive diagnosis of gastrinoma requires histologic and immunocytochemical evaluation of a pancreatic mass excised at surgery. Finding increased baseline serum gastrin concentrations from blood obtained after an overnight fast increases the suspicion of gastrinoma. Additional differential diagnoses for increased serum gastrin concentration include gastric outflow tract obstruction, renal failure, short-bowel syndrome, chronic gastritis, hepatic disease, and animals receiving antacid therapy (e.g., H<sub>2</sub>-receptor antagonists, proton pump inhibitors). Baseline serum gastrin concentrations may vary, with occasional values in the reference range in animals with gastrinoma. Provocative testing (e.g., secretin stimulation test, calcium challenge test) may be considered in dogs strongly suspected of having gastrinoma but with normal baseline serum gastrin concentrations. Exploratory laparotomy should also be considered. (See Suggested Readings for more information on provocative testing).

#### **Treatment**

Treatment should be directed at surgical excision of the tumor and control of gastric acid hypersecretion. Gastrointestinal tract ulceration can usually be managed by reducing gastric hyperacidity through the administration of H<sub>2</sub>-receptor antagonists (e.g., ranitidine, famotidine), proton pump inhibitors (e.g., omeprazole), gastrointestinal tract protectants (e.g., sucralfate), or prostaglandin E<sub>1</sub> analogs (e.g., misoprostol). (See Chapter 30 for more information on these gastrointestinal tract drugs.) Surgical resection of an ulcer may be required, especially if the ulcer has perforated the bowel. Surgical resection of the tumor is necessary to obtain a cure, although metastasis to the liver, regional lymph nodes, and mesentery is common. Even if metastatic disease is present, tumor debulking may enhance the success of medical therapy.

# **Prognosis**

The long-term prognosis for gastrinoma is guarded to poor. Evidence of metastasis was present in 76% of reported dogs and cats at the time a gastrinoma was diagnosed. Reported survival time in dogs and cats treated surgically, medically, or both ranged from 1 week to 18 months (mean, 4.8 months). However, the short-term prognosis has improved with the advent of drugs that can reduce gastric hyperacidity (e.g., ranitidine, famotidine) and protect and promote healing of the ulcers (e.g., sucralfate, misoprostol).

# HYPERADRENOCORTICISM IN DOGS

# **Etiology**

Hyperadrenocorticism (Cushing's disease) is classified as pituitary dependent, adrenocortical dependent, or iatrogenic (i.e., resulting from excessive administration of glucocorticoids by the veterinarian or client).

# PITUITARY-DEPENDENT HYPERADRENOCORTICISM

Pituitary-dependent hyperadrenocorticism (PDH) is the most common cause of spontaneous hyperadrenocorticism, accounting for approximately 80% to 85% of cases. A functional adrenocorticotropic hormone (ACTH)-secreting pituitary tumor is found at necropsy in approximately 85% of dogs with PDH. Adenoma of the pars distalis is the most common histologic finding, with a smaller percentage of dogs diagnosed with adenoma of the pars intermedia and a few dogs diagnosed with functional pituitary carcinoma. Approximately 50% of dogs with PDH have pituitary tumors less than 3 mm in diameter, and most of the remaining dogs, specifically those without central nervous system (CNS) signs, have tumors 3 to 10 mm in diameter at the time PDH is diagnosed. Approximately 10% to 20% of dogs have pituitary tumors (i.e., macrotumors) exceeding 10 mm in diameter at the time PDH is diagnosed. These tumors have the potential to compress or invade adjacent structures and cause neurologic signs as they expand dorsally into the hypothalamus and thalamus (Fig. 53-1).

Excessive secretion of ACTH causes bilateral adrenocortical hyperplasia and excess cortisol secretion from the adrenal cortex (Fig. 53-2). Because normal feedback inhibition of ACTH secretion by cortisol is missing, excessive ACTH secretion persists despite increased adrenocortical secretion of cortisol. Episodic secretion of ACTH and cortisol is common and results in fluctuating plasma concentrations that may at times be within the reference range.

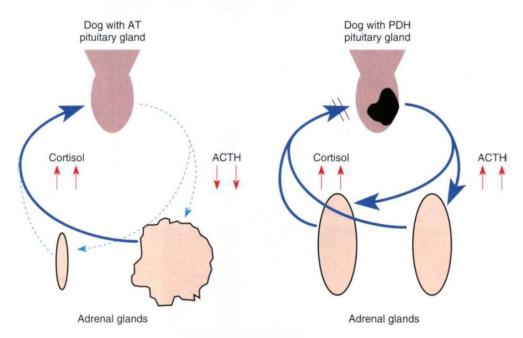

#### ADRENOCORTICAL TUMORS

Adrenocortical tumors (ATs) account for the remaining 15% to 20% of dogs with spontaneous hyperadrenocorticism.

#### FIG 53-1

**A**, A 10-year-old male castrated mixed-breed dog with pituitary-dependent hyperadreno-corticism. Initial clinical signs of polyuria, polydipsia, and endocrine alopecia progressed to severe stupor, anorexia, adipsia, weight loss, and loss of body temperature regulation. **B**, Cross-section of the brain from the dog in **A** showing a pituitary macroadenoma that is severely compressing the surrounding brain structures.

#### FIG 53-2

The pituitary-adrenocortical axis in dogs with a functioning adrenocortical tumor (AT; *left*) and in dogs with pituitary-dependent hyperadrenocorticism (PDH; *right*). Excess cortisol secretion from an AT causes pituitary suppression, decreased plasma adrenocorticotropic hormone (ACTH) concentration, and atrophy of the contralateral adrenal gland. Dogs with PDH have excess ACTH secretion, usually from a functional pituitary adenoma, which causes bilateral adrenomegaly and excess plasma cortisol concentrations.

Adrenocortical adenoma and carcinoma occur with equal frequency. There are no consistent clinical or biochemical features that help distinguish dogs with functional adrenal adenomas from those with adrenal carcinomas, although carcinomas tend to be larger than adenomas on abdominal ultrasound. Adrenocortical carcinomas may invade adjacent structures (e.g., phrenicoabdominal vein, caudal vena cava, kidney) or metastasize to the liver and lung.

Bilateral ATs can occur in dogs but are rare. A nonfunctional AT or an AT causing hyperadrenocorticism and a pheochromocytoma in the contralateral gland is a more common cause of bilateral adrenal masses in dogs. Macronodular hyperplasia of the adrenals has also been identified in dogs. The adrenals in such animals are usually grossly enlarged, with multiple nodules of varying sizes within the adrenal cortex. The exact pathogenesis of this latter syn-

drome is unclear, although most cases in dogs are presumed to represent an anatomic variant of PDH. Increased plasma 17-OH-progesterone concentrations have also been documented in dogs with an adrenal mass and clinical manifestations of hyperadrenocorticism but normal plasma cortisol concentrations after administration of ACTH or dexamethasone (see the section on atypical Cushing's syndrome, p. 830).

Adrenocortical tumors causing hyperadrenocorticism (ATHs) are autonomous and functional and randomly secrete excessive amounts of cortisol independent of pituitary control. The cortisol produced by these tumors suppresses circulating plasma ACTH concentrations, causing cortical atrophy of the uninvolved adrenal and atrophy of all normal cells in the involved adrenal (see Fig. 53-2). This atrophy creates asymmetry in the size of the adrenal glands, which can be identified by abdominal ultrasonography. Most, if not all, of these tumors appear to retain ACTH receptors and respond to administration of exogenous ACTH. ATHs are typically unresponsive to manipulation of the hypothalamic-pituitary axis with glucocorticoids such as dexamethasone.

#### IATROGENIC HYPERADRENOCORTICISM

Iatrogenic hyperadrenocorticism typically results from the excessive administration of glucocorticoids to control allergic or immune-mediated disorders. It can also develop as a result of the administration of eye, ear, or skin medications containing glucocorticoids, especially in small dogs (weight less than 10 kg) receiving them long term. Because the hypothalamic-pituitary-adrenocortical axis is normal, the prolonged excessive administration of glucocorticoids suppresses circulating plasma ACTH concentrations, causing bilateral adrenocortical atrophy. In these animals ACTH stimulation test results are consistent with spontaneous hypoadrenocorticism despite clinical signs of hyperadrenocorticism.

#### Clinical Features

#### **SIGNALMENT**

Hyperadrenocorticism typically develops in dogs 6 years of age and older (median age 10 years) but has been documented in dogs as young as 1 year. There is no apparent sex-related predisposition, although AT appears to be diagnosed more commonly in female dogs. PDH and ATH have been diagnosed in numerous breeds. All Poodle breeds, Dachshunds, various Terrier breeds, German Shepherd Dogs, Beagles, and Labrador Retrievers are commonly represented, and Boxers and Boston Terriers appear to be at increased risk for PDH. PDH tends to occur more frequently in smaller dogs; 75% of dogs with PDH weigh less than 20 kg. Approximately 50% of dogs with functional ATH weigh more than 20 kg.

#### **CLINICAL SIGNS**

The most common clinical signs are polyuria, polydipsia, polyphagia, panting, abdominal enlargement, endocrine alo-

pecia, mild muscle weakness, and lethargy (Fig. 53-3; Table 53-1). Most dogs exhibit several, but not all, of these clinical signs. The more signs evident in the history, the greater the index of suspicion for hyperadrenocorticism. Additional findings on physical examination (see Table 53-1) help establish the diagnosis.

Dogs are occasionally seen because of isolated polyuria and polydipsia, bilaterally symmetric endocrine alopecia, or panting. There may be no other historic or physical examination findings consistent with hyperadrenocorticism. The diagnosis of hyperadrenocorticism is not readily apparent in these dogs. Fortunately, hyperadrenocorticism is a differential diagnosis for polyuria and polydipsia, endocrine alopecia, and panting and will be identified as the clinician works through the differentials for these problems. Similarly, hyperadrenocorticism causes insulin resistance and can lead to the development of diabetes mellitus. Clinical signs (other than polyuria and polydipsia) and physical examination findings suggestive of hyperadrenocorticism are often missing in diabetic dogs with concurrent hyperadrenocorticism. A clinical suspicion for hyperadrenocorticism develops after critical evaluation of routine blood test results (e.g., increased serum alkaline phosphatase [ALP] activity, isosthenuric urine) or after resistance to insulin treatment is identified.

There were no neurologic signs present at the time the MRI scan was performed. **B,** Postgadolinium administration MRI scan of an 8-year-old Boston Terrier with PDH, a large pituitary mass invading the brainstem, and signs of disorientation, ataxia, and circling. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, St Louis, 2004, WB Saunders.)

PHILIPS GYROSCAN S15

#### PITUITARY MACROTUMOR SYNDROME

Neurologic signs may develop in dogs with PDH as a result of expansion of the pituitary tumor into the hypothalamus and thalamus (see Fig. 53-1). Neurologic signs may be present at the time PDH is diagnosed but usually develop 6 months or longer after PDH is identified. The most common neurologic sign is a dull, listless attitude (i.e., stupor). Additional signs of pituitary macroadenoma include inappetence, aimless wandering, pacing, ataxia, head pressing, circling, and behavioral alterations. In the event of severe compression of the hypothalamus, abnormalities related to dysfunction of the autonomic nervous system develop, including adipsia, loss of temperature regulation, erratic heart rate, and inability to be roused from a sleeplike state. Identification of a pituitary macrotumor requires computed tomography (CT) or magnetic resonance imaging (MRI; Fig. 53-4). There are no biochemical or endocrine test results that reliably correlate with the size of the pituitary tumor.

# MEDICAL COMPLICATIONS: PULMONARY THROMBOEMBOLISM

Several medical complications can develop secondary to prolonged cortisol excess (Box 53-1). The most worrisome is pulmonary thromboembolism (PTE), which generally occurs in dogs undergoing adrenalectomy for AT. Thromboemboli may also affect the kidney, gastrointestinal tract, heart, and CNS. There is no apparent correlation between control of hyperadrenocorticism and development of thromboemboli. Factors predisposing to the development of PTE in dogs with hyperadrenocorticism include inhibition of fibrinolysis (corticosteroids stimulate the release of plasminogen activator inhibitors), systemic hypertension, protein-losing glomerulonephropathy, decreased serum antithrombin III concentrations, increased concentrations of several coagulation

Pulmonary thromboembolism

Pituitary macrotumor syndrome

factors, and an increased hematocrit value. Clinical signs of PTE include acute respiratory distress; orthopnea; and, less commonly, a jugular pulse. Thoracic radiographs may reveal no abnormalities, or they may show hypoperfusion, alveolar pulmonary infiltrates, or a pleural effusion. There may be an increased diameter and blunting of the pulmonary arteries, absence of perfusion of the obstructed pulmonary vasculature, and overperfusion of the unobstructed pulmonary vasculature. Normal thoracic radiograph findings in a dyspneic dog that does not have a large airway obstruction suggest a diagnosis of PTE. Arterial blood gas analysis typically reveals a decrease in the partial pressures of arterial oxygen and carbon dioxide, and mild metabolic acidosis. Thrombosis may be confirmed by angiography of the lungs or by radionuclear lung scanning. Therapy consists of general supportive care, oxygen, anticoagulants, and time (see Chapter 12). The prognosis for dogs with PTE is guarded to grave. If dogs do recover, it typically takes 5 to 10 days before they can be safely removed from oxygen support.

# Diagnosis

A thorough evaluation should be done in any dog suspected of having hyperadrenocorticism and should include a complete blood count (CBC); serum biochemistry panel; urinalysis with bacterial culture; and, if available, abdominal ultrasonography. Results of these tests will increase or decrease the index of suspicion for hyperadrenocorticism; identify common concurrent problems (e.g., urinary tract infection); and, in the case of ultrasonography, provide valuable information for localizing the cause of the disorder (i.e., PDH versus AT). Endocrine studies required to confirm the diagnosis and localize the cause of the disorder can then be performed.

## **CLINICAL PATHOLOGY**

Common clinicopathologic alterations caused by hyperadrenocorticism are listed in Box 53-2. An increase in ALP activity and cholesterol concentration is the most reliable indicator of hyperadrenocorticism. The major contributor to increased serum ALP is the corticosteroid-induced isoenzyme of ALP derived from the bile canalicular membrane of hepatocytes. Approximately 85% of dogs with hyperadrenocorticism have ALP activities that exceed 150 IU/L; values in excess of 1000 IU/L are common, and values in excess of 10,000 IU/L are occasionally identified. There is no correlation between the magnitude of increase in serum ALP activity and the severity of hyperadrenocorticism, response to therapy, or prognosis. There is also no correlation between the magnitude of increase in serum ALP activity and hepatocellular death or hepatic failure. The ALP activity can be normal in some dogs with hyperadrenocorticism, and an increase in ALP activity by itself is not diagnostic for hyperadrenocorticism. Similarly, an increase in the activity of the corticosteroid-induced isoenzyme of alkaline phosphatase (SIAP) is not a finding specific to hyperadrenocorticism or exogenous glucocorticoid administration; an increase in SIAP activity occurs commonly with many disorders, including diabetes mellitus, primary hepatopathies, pancreatitis,

BOX 53-2

Clinicopathologic Abnormalities Commonly Identified in Dogs with Hyperadrenocorticism

Neutrophilic leukocytosis
Eosinopenia
Lymphopenia
Mild erythrocytosis
Increased alkaline phosphatase activity
Increased alanine aminotransferase activity
Hypercholesterolemia
Lipemia
Hyperglycemia
Hyposthenuria, isosthenuria
Urinary tract infection
Proteinuria
Mild increase in pre- and postprandial bile acids

congestive heart failure, and neoplasia as well as in dogs receiving certain drugs (e.g., anticonvulsants). However, finding no SIAP in the serum may be of diagnostic value in ruling out hyperadrenocorticism.

Urine specific gravity is typically less than 1.020 in dogs with hyperadrenocorticism that have free access to water. Water-deprived hyperadrenal dogs maintain the ability to concentrate urine, although usually the concentrating ability remains less than normal. As such, urine specific gravities of 1.025 to 1.035 may be identified if urine is obtained after water has been withheld from the dog.

Proteinuria is a common finding in dogs with untreated hyperadrenocorticism. Proteinuria may be caused by glucocorticoid-induced systemic and glomerular hypertension, glomerulonephritis, or glomerulosclerosis. Urine protein: creatinine ratios are usually less than 4, although values in excess of 8 have been identified. Proteinuria decreases and often resolves in response to treatment of hyperadrenocorticism.

Urinary tract infection is a common sequela of hyperadrenocorticism. Hyposthenuria and the antiinflammatory effects of glucocorticoids commonly interfere with the identification of bacteria or inflammatory cells in the urine. Whenever hyperadrenocorticism is suspected, antepubic cystocentesis with bacterial culture of the urine and antibiotic sensitivity testing is strongly recommended, regardless of the urinalysis findings.

#### DIAGNOSTIC IMAGING

Abnormalities identified by thoracic and abdominal radiography and by abdominal ultrasonography are listed in Box 53-3. The most consistent radiographic findings in dogs with hyperadrenocorticism are enhanced abdominal contrast secondary to increased fat distribution in the abdomen; hepatomegaly caused by steroid hepatopathy; an enlarged urinary bladder secondary to the polyuric state; and dystrophic calcification of the trachea, bronchi, and occasionally the skin and abdominal blood vessels. The most important but least common radiographic finding is a soft-tissue mass or calcification in the area of an adrenal gland (Fig. 53-5). These findings are suggestive of an adrenal tumor. Approximately 50% of ATH are calcified; the frequency of calcification is equally distributed between adenoma and carcinoma. Metastasis of an adrenocortical carcinoma to the pulmonary parenchyma is occasionally evident on thoracic radiographs.

Abdominal ultrasonography is used to evaluate the size and shape of the adrenals and to search for additional abnormalities in the abdomen (e.g., cystic calculi, tumor thrombus; Fig. 53-6). Finding bilaterally symmetric normal-size or large adrenals (defined as having a maximum width greater than 0.8 cm) in a dog with hyperadrenocorticism is evidence for adrenal hyperplasia caused by PDH. The adrenal glands in dogs with PDH are similar but not exactly the same in size and shape; should have smooth, not irregular borders; can exceed 2 cm in maximum width; may have a bulbous cranial or caudal pole; and do not invade surrounding blood vessels or organs (see Fig. 53-6). An AT is typically identified as an

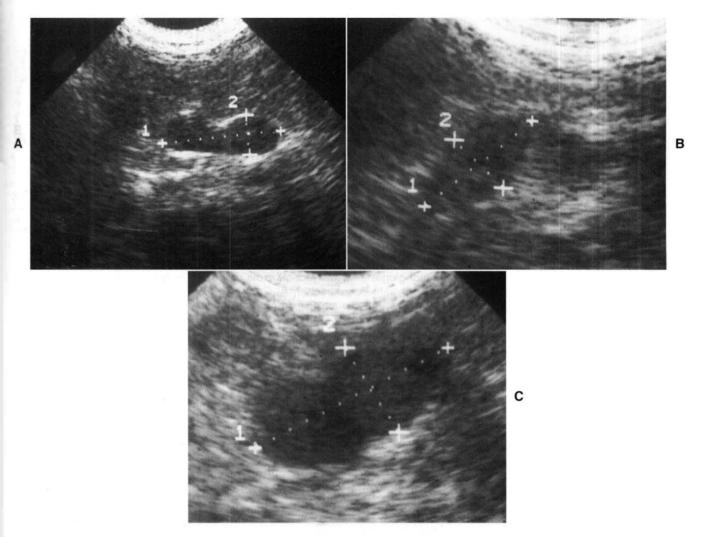

FIG 53-5

**A,** Lateral radiograph from a dog with adrenal-dependent hyperadrenocorticism showing a calcified adrenal mass cranial to the kidney (arrow). **B,** Ventrodorsal radiograph from a dog with adrenal-dependent hyperadrenocorticism showing a calcified adrenal mass craniomedial to the kidney and lateral to the spine (arrow). Compression of the abdomen in the region of the adrenal gland with a paddle has enhanced radiographic contrast, allowing better visualization of the adrenal mass.

adrenal mass (Fig. 53-7). Size is quite variable, ranging from 1.5 to greater than 8 cm in maximum width. Small adrenal masses (i.e., less than 3 cm in maximum width) often maintain a smooth contour and may distort only a portion of the adrenal gland; one or both poles of the adrenal gland may still appear normal. With large adrenal masses (typically greater than 3 cm in maximum width), the adrenal gland usually becomes distorted and unrecognizable, the contour of the gland becomes irregular, and compression and/or

invasion into adjacent blood vessels and organs may occur (Fig. 53-8). These changes suggest adrenocortical carcinoma. Identification of calcification within the mass does not differentiate adenoma from carcinoma. Generally, the larger the mass, the more likely it is carcinoma. Asymmetry in the size of the adrenal glands is evident (see Fig. 53-2). Ideally, the contralateral unaffected adrenal should be small or undetectable (maximum width typically less than 0.3 cm) as a result of AT-induced adrenocortical atrophy (see Fig. 53-7),

Р

#### FIG 53-6

Ultrasound images of the adrenal gland in three dogs with pituitary-dependent hyperadre-nocorticism (PDH) illustrating the differences in size and shape of the adrenal gland that can occur with PDH. **A,** The adrenal gland in this dog has maintained the typical kidney-bean shape often identified in normal dogs. However, the maximum diameter of the gland was enlarged at 0.85 cm. The contralateral adrenal gland was similar in size and shape. **B,** The adrenal gland in this dog is uniformly thickened and appears plump rather than kidney-bean shaped. The maximum diameter of the gland was 1.2 cm. The contralateral adrenal gland was similar in size and shape. **C,** Although the adrenal gland has maintained some semblance of a kidney-bean shape in this dog, the gland has undergone marked enlargement, with a maximum diameter of 2.4 cm. The contralateral adrenal gland was similar in size and shape.

although a normal-size contralateral adrenal gland does not rule out hyperadrenocorticism caused by AT. Identification of an adrenal mass and a normal-to-large contralateral adrenal gland in a dog with clinical signs supportive of hyperadrenocorticism suggests the possibility of PDH and a concurrent adrenal mass that may be a pheochromocytoma, a functional adrenocortical tumor, or a nonfunctional AT (Fig. 53-9). Finding normal-size adrenal glands in a dog with confirmed hyperadrenocorticism is most consistent with a diagnosis of PDH. Finding bilateral adrenomegaly with the appearance of multiple nodules of varying size is suggestive

of macronodular hyperplasia (Fig. 53-10). Bilateral adrenal macronodular hyperplasia is believed to represent an anatomic variant of PDH. Failure to identify either adrenal is considered an inconclusive finding, and ultrasonography should be repeated at a later time.

CT and MRI can be used to evaluate the pituitary gland for a macroadenoma and assess the size and symmetry of the adrenal glands. Contrast enhancement using an iodinated contrast agent (CT) or gadolinium (MRI) given by continuous intravenous (IV) infusion during the imaging procedure aids in the identification of a pituitary macroad-

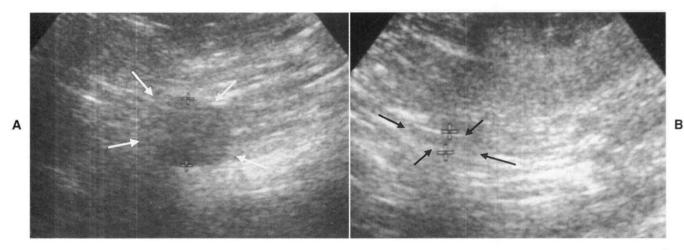

FIG 53-7

Ultrasound images of the adrenal glands in an 11-year-old male castrated Golden Retriever with adrenal-dependent hyperadrenocorticism. **A,** Cortisol-secreting tumor affecting the right adrenal gland (*arrows*). The maximum diameter of the adrenal mass was 1.6 cm. **B,** The left adrenal gland has undergone marked atrophy (*arrows* and *crosses*) as a result of suppression of pituitary adrenocorticotropic hormone secretion after negative feedback inhibition caused by the adrenocortical tumor. The maximum diameter of the left adrenal gland was less than 0.2 cm.

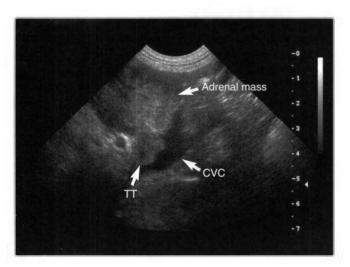

FIG 53-8

Ultrasound image of a mass affecting the left adrenal gland (adrenal mass) and extending into the lumen of the caudal vena cava (CVC) creating a tumor thrombus (TT) in a 9-year-old male Standard Poodle. The maximum width of the adrenal mass was 3.8 cm. The histopathologic diagnosis was pheochromocytoma.

enoma and the adrenal glands during CT and MRI examination, respectively (see Fig. 53-4). The primary indications for CT or MRI are to confirm the presence of a visible pituitary tumor in a dog with clinical signs suggestive of macrotumor (see the section on pituitary macrotumor syndrome, p. 814) or in dogs diagnosed with PDH in which the client is willing to consider radiation treatment should a pituitary mass be

identified (see the section on radiation therapy, p. 829) and to assess the size of an adrenal mass and extent of infiltration of the mass into surrounding blood vessels and organs before adrenalectomy. MRI is superior to CT in detecting small pituitary tumors; in detecting associated tumor features such as edema, cysts, hemorrhage, and necrosis; and in imaging the adrenal glands.

# TESTS OF THE PITUITARY-ADRENOCORTICAL AXIS

The clinical signs, physical examination findings, and clinicopathologic alterations usually establish a presumptive diagnosis of hyperadrenocorticism, and results of an abdominal ultrasound provide valuable information regarding probable location of the lesion. Tests to establish the diagnosis of hyperadrenocorticism include the urine cortisol: creatinine ratio (UCCR), the ACTH stimulation test, the low-dose dexamethasone suppression (LDDS) test, and the oral dexamethasone suppression test (Table 53-2). Baseline serum cortisol measurement by itself is of no diagnostic value in diagnosing hyperadrenocorticism. Discriminatory tests are used to identify the etiology (i.e., PDH versus AT) in dogs with confirmed hyperadrenocorticism and include the low- and high-dose dexamethasone suppression test and baseline endogenous ACTH concentration. The most commonly used tests in our hospital are the UCCR, LDDS test, and abdominal ultrasound. An endogenous ACTH concentration is evaluated when abdominal ultrasound suggests an adrenal mass but results of the LDDS test are inconclusive or suggest PDH and when an adrenal mass is identified with contralateral adrenomegaly.

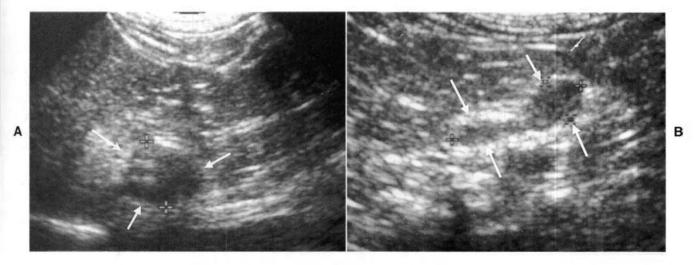

FIG 53-9

Ultrasound images of the adrenal glands in a 10-year-old female spayed Bichon Frise presented for acute onset of vomiting. **A**, An unexpected mass involving the right adrenal gland, measuring 1.4 cm in maximum diameter, was identified (arrows). **B**, The left adrenal gland was normal in size and shape (arrows); the maximum diameter was 0.6 cm. The normal-size left adrenal gland suggests that the right adrenal mass is either a pheochromocytoma or is nonfunctional. Results of routine blood work and tests for hyperadrenocorticism were normal.

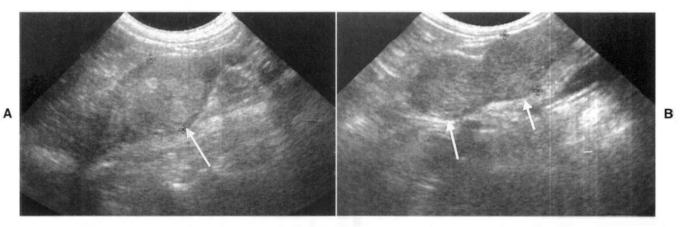

FIG 53-10

Ultrasound images of the adrenal glands (arrows) in an 11-year-old female spayed Shih Tzu. The right adrenal gland (A) measured 1.8 cm in maximum diameter and had a nodular echogenic pattern. In contrast, the left adrenal gland (B) had a large nodule located in each pole of the gland; each measured approximately 1.4 cm in maximum diameter. Tests of the pituitary-adrenocortical axis were diagnostic for pituitary-dependent hyperadrenocorticism; this finding, in conjunction with the findings on ultrasound, suggests macronodular hyperplasia of the adrenal glands.

False-positive and false-negative test results occur with all of the diagnostic tests for hyperadrenocorticism. When the results are unexpected or questionable, another diagnostic test can be performed or the same diagnostic test repeated, preferably after waiting several months. Occasionally, results of different diagnostic tests performed in the same dog are contradictory. The decision to perform discriminatory tests or to initiate therapy should depend on the clinician's index of suspicion for the disease formulated from a review of the history, findings on physical examination, and

results of diagnostic tests. If there is doubt or uncertainty about the diagnosis, therapy for hyperadrenocorticism should be withheld and the dog reevaluated several months later.

#### **Urine Cortisol: Creatinine Ratio**

The UCCR is an excellent initial screening test for hyperadrenocorticism in dogs. Ideally, the UCCR should be determined from free-catch urine samples obtained by the client in the nonstressful home environment. The stress associated

<sup>†</sup>Strongly suggestive of hyperadrenocorticism.

<sup>‡</sup> Suggestive of hyperadrenocorticism.

Urinary corticoid: creatinine (C:C) ratio measured in 12 pet dogs before and after a visit to a referral clinic for orthopedic examination (A) and in 9 healthy pet dogs before, during, and after a 1.5-day hospitalization at a referral clinic (B). The arrows indicate time of visit to the referral clinic. Note the increase in the urinary C:C ratio in a few dogs affiliated with a visit to a veterinary practice. (From van Vonderen IK et al: Influence of veterinary care on the urinary corticoid:creatinine ratio in dogs, J Vet Intern Med 12:431, 1998.)

with driving the dog to the veterinary hospital and having the dog undergo a physical examination before collecting urine can increase the test results (Fig. 53-11). The UCCR is increased in dogs with hyperadrenocorticism compared with healthy dogs. Normal UCCR test results can occur in dogs with hyperadrenocorticism but are uncommon. Unfortunately, the specificity of the UCCR is only 20% in dogs. The UCCR is often increased in dogs with nonadrenal illness and in dogs with clinical signs consistent with hyperadrenocorticism but with a normal pituitary-adrenocortical axis (Fig. 53-12). A normal UCCR is a strong finding against hyperadrenocorticism and can be used as a screening test for normalcy; however, an increased UCCR is not diagnostic of hyperadrenocorticism. Additional tests are indicated when the UCCR is increased or when the UCCR is normal but the clinical picture strongly suggests hyperadrenocorticism.

# Low-Dose Dexamethasone Suppression Test

In the normal dog relatively small doses of dexamethasone given intravenously can inhibit pituitary secretion of ACTH, causing a prolonged decline in the serum cortisol concentration (Fig. 53-13). Dexamethasone is used because it does not interfere with the radioimmunoassays used to measure cortisol. The abnormal pituitary in dogs with PDH is somewhat resistant to the negative feedback action of dexamethasone, and the metabolic clearance of dexamethasone may be abnormally accelerated as well. The administration of a small dose of dexamethasone to a dog with PDH causes the serum cortisol concentration to be variably suppressed; however, it is no longer suppressed by 8 hours after dexamethasone administration, compared with the response seen in normal dogs. ATH function independently of ACTH control, and dexamethasone does not affect the serum cortisol concentration, regardless of the dose or time of blood

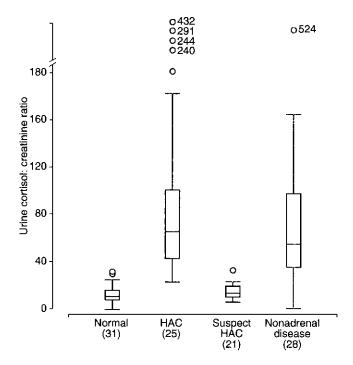

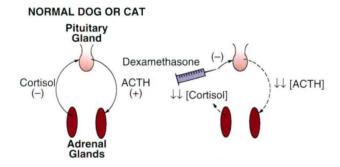

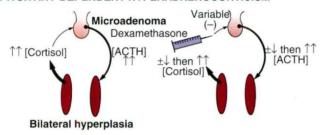

FIG 53-12

Box plots of the urine cortisol: creatinine ratios found in normal dogs, dogs with hyperadrenocorticism (HAC), dogs in which hyperadrenocorticism was initially suspected but that did not have the disease (suspect HAC), and dogs with a variety of severe, nonadrenal diseases. For each box plot, T-bars represent the main body of data, which in most instances are equal to the range. Each box represents an interquartile range (twenty-fifth to seventy-fifth percentile). The horizontal bar in each box is the median. Open circles represent outlying data points. Numbers in parentheses indicate the numbers of dogs in each group. (From Smiley LE et al: Evaluation of a urine cortisol: creatinine ratio as a screening test for hyperadrenocorticism in dogs, J Vet Intern Med 7:163, 1993.)

#### PITUITARY-DEPENDENT HYPERADRENOCORTICISM

# ADRENOCORTICAL NEOPLASIA Dexamethasone (-) [ACTH] | (ACTH) | (A

#### FIG 53-13

Adrenal tumor

Effects of dexamethasone administration on the pituitary-adrenocortical axis in healthy dogs or cats and in dogs or cats with either pituitary-dependent hyperadrenocorticism (PDH) or adrenocortical neoplasia. In PDH dexamethasone may initially suppress pituitary adrenocorticotropic hormone (ACTH) secretion, but the suppression is short-lived. The plasma cortisol concentrations initially decline but increase above normal within 2 to 6 hours of dexamethasone administration. In adrenocortical neoplasia pituitary ACTH secretion is already suppressed; thus dexamethasone has no effect.

sampling because pituitary corticotrophs are already suppressed and blood ACTH concentration is undetectable.

The LDDS test is a reliable diagnostic test for differentiating normal dogs from those with hyperadrenocorticism and may identify PDH. Sensitivity and specificity are approximately 90%. The LDDS does not identify iatrogenic hyperadrenocorticism, nor is it used to assess a dog's response to mitotane (lysodren) or trilostane therapy. A normal or inconclusive LDDS test result does not by itself rule out hyperadrenocorticism. If hyperadrenocorticism is suspected, additional tests of the pituitary-adrenocortical axis should be performed. Similarly, an abnormal LDDS test result does not by itself confirm hyperadrenocorticism. Results of the LDDS test may be affected by concurrently administered

anticonvulsant drugs, stress, excitement, exogenous glucocorticoids, and nonadrenal disease; the more severe the nonadrenal disease, the more likely the LDDS test result will be falsely positive. When performing the LDDS test, the clinician must ensure that all stressors are kept to a minimum; other procedures should not be performed until the test is completed, and the effect of concurrent clinical problems should be considered when interpreting results.

The protocol for the LDDS test and interpretation of results are described in Table 53-2. The clinician may use either dexamethasone sodium phosphate or dexamethasone in polyethylene glycol. The 8-hour postdexamethasone serum cortisol concentration is used to confirm hyperadrenocorticism. Normal dogs typically have serum cortisol values less than 1.0 g/dl, whereas dogs with PDH and AT have serum cortisol concentrations greater than 1.5 | g/dl 8 hours after dexamethasone administration. In general, the higher the 8-hour postdexamethasone serum cortisol concentration is above 1.5 µ g/dl, the more supportive the test result is for hyperadrenocorticism. Cortisol concentrations between 1.0 and 1.5 µ g/dl are nondiagnostic. If results are in the nondiagnostic range, the clinician must rely on other information, including other tests of the pituitary-adrenocortical axis, to determine if hyperadrenocorticism is the correct diagnosis.

If the 8-hour postdexamethasone serum cortisol value supports a diagnosis of hyperadrenocorticism, the 4-hour serum cortisol value may then be of value in identifying PDH. Low doses of dexamethasone suppress pituitary ACTH secretion and serum cortisol concentrations in approximately 60% of dogs with PDH. Suppression does not occur in dogs with AT, nor does it occur in approximately 40% of dogs with PDH. Suppression is defined as a 4-hour postdexamethasone serum cortisol concentration of less than 1.5 | g/ dl, a 4-hour postdexamethasone serum cortisol concentration less than 50% of the baseline concentration, or an 8hour postdexamethasone serum cortisol concentration less than 50% of the baseline concentration. Any dog with hyperadrenocorticism that meets one or more of these criteria most likely has PDH. If none of these criteria is met, then results of the LDDS test are consistent with lack of suppression but not informative in terms of whether it is pituitary or adrenal in origin. Differentiation between PDH and AT must rely on results of abdominal ultrasound, the HDDS test, or plasma endogenous ACTH concentration.

# **Oral Dexamethasone Suppression Test**

An alternative at-home oral dexamethasone suppression test has been used for years at the University of Utrecht, The Netherlands. This test relies entirely on results of UCCRs to establish the diagnosis of hyperadrenocorticism and to identify PDH. The client is instructed to collect two urine samples from the dog on 2 consecutive mornings and store them in the refrigerator. After collection of the second urine sample, the client should administer 3 doses of dexamethasone (0.1 mg/kg/dose) to the dog orally at 8-hour intervals. Urine is collected on the morning of the third day, and all three

samples are delivered to the veterinarian for measurement of UCCRs. The first two urine samples are the screening test to diagnose hyperadrenocorticism. Abnormal values support hyperadrenocorticism; normal values rule out the disease. If both values are abnormal, then the average of the two values is used as the baseline value and compared with the third value obtained after dexamethasone administration. The dog is described as having responded to dexamethasone (suppressed) if the UCCR result from the third urine sample is less than 50% of the baseline value. Dogs meeting this criteria have results consistent with PDH, whereas those failing to demonstrate suppression could have either AT or PDH.

# Adrenocorticotropic Hormone Stimulation Test

The ACTH stimulation test is used to establish the diagnosis of hyperadrenocorticism and hypoadrenocorticism, identify iatrogenic hyperadrenocorticism, identify atypical hyperadrenocorticism (see p. 830), and monitor mitotane and trilostane treatment. ACTH stimulation test results do not distinguish between PDH and AT. In our experience ACTH stimulation test results are clearly abnormal in approximately 30%, in the borderline range in another 30% and within the reference range in approximately 40% of dogs with PDH. Identification of ACTH stimulation test results in the borderline range is common, and clearly abnormal test results occur in dogs that do not have hyperadrenocorticism. Because of problems with sensitivity and specificity combined with the high cost of ACTH, I do not routinely use the ACTH stimulation test when evaluating dogs for hyperadrenocorticism.

The protocol for the ACTH stimulation test is given in Table 53-2. When synthetic ACTH is being used, a lower dose (5 μg/kg, administered intravenously or intramuscularly) is also effective and the unused reconstituted ACTH can be stored frozen at -20°C in plastic syringes for 6 months with no adverse effects on bioactivity of the ACTH. Four ranges of values are used in the interpretation of the ACTH stimulation test (Fig. 53-14). Post-ACTH serum cortisol values between 6 and 18 | g/dl are within the normal reference range, values of 5 µg/dl and below are suggestive of iatrogenic hyperadrenocorticism or hypoadrenocorticism, values between 18 and 24 µg/dl are considered borderline for hyperadrenocorticism, and values greater than 24 µg/dl are supportive of hyperadrenocorticism, assuming the clinical findings and clinicopathologic data are consistent with the disease. An increased post-ACTH serum cortisol value, especially one between 18 and 24 µg/dl, does not by itself confirm a diagnosis of hyperadrenocorticism, especially if the clinical features and clinicopathologic data are not consistent with the diagnosis.

Post-ACTH serum cortisol concentrations that do not increase above the preadministration value suggest iatrogenic hyperadrenocorticism or spontaneous hypoadrenocorticism, especially if the cortisol values are below the normal baseline range (i.e., less than 5 µg/dl; see Fig. 53-14). A history of recent glucocorticoid administration and the

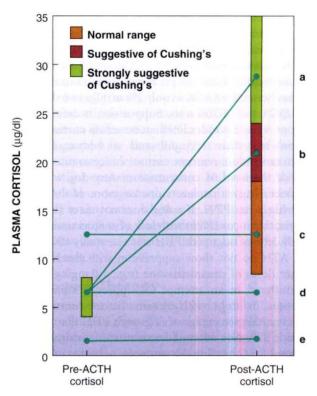

FIG 53-14

Interpretation of the adrenocorticotropic hormone (ACTH) stimulation test in dogs. Ideally, dogs with Cushing's syndrome have an increased post-ACTH administration cortisol concentration (line a). Post-ACTH cortisol values that fall into the "gray zone" (line b) could be consistent with Cushing's syndrome or result from the effects of concurrent illness or chronic stress. Post-ACTH cortisol values may also fall into the normal range in dogs with Cushing's syndrome. The absence of a response to ACTH stimulation is suggestive of adrenocortical neoplasia (lines c and d) or iatrogenic hyperadrenocorticism (lines d and e). History and physical examination findings should differentiate between these possibilities.

clinical presentation of the dog can help differentiate iatrogenic hyperadrenocorticism from spontaneous hypoadrenocorticism. In rare instances a dog with AT will have a minimal cortisol response to ACTH; however, its pre-ACTH and post-ACTH administration serum cortisol concentrations are within or above the reference range.

# High-Dose Dexamethasone Suppression Test

ATs function independently of pituitary ACTH; therefore, regardless of the dose, dexamethasone should never suppress the serum cortisol concentration if the source of the cortisol is an AT. In contrast, dexamethasone-induced suppression of ACTH secretion from a pituitary tumor is variable and may depend on the dexamethasone dose. The administration of increased amounts of dexamethasone should eventually suppress pituitary ACTH secretion in most dogs with PDH. The protocol for the high-dose dexamethasone suppression

(HDDS) test is similar to that for the LDDS test protocol, except that a higher dose (i.e., 0.1 mg/kg of body weight) of dexamethasone is used in an attempt to suppress pituitary ACTH secretion (see Table 53-2). Obtaining a 4-hour postdexamethasone blood sample is optional; in our experience, this has been informative in only 2% of dogs tested with both the LDDS and HDDS tests. Suppression is defined as a 4hour or 8-hour postdexamethasone serum cortisol concentration less than 1.5 µg/dl and a 4-hour or 8-hour postdexamethasone serum cortisol concentration less than 50% of the baseline concentration. Any dog with hyperadrenocorticism that meets one or more of these criteria most likely has PDH. If a dog does not meet any of these criteria, this is consistent with lack of suppression. Approximately 25% of dogs with PDH and essentially 100% of dogs with ATH do not show suppression with the HDDS test. Higher doses of dexamethasone (e.g., 1.0 mg/kg) could be administered in an attempt to suppress pituitary ACTH secretion in dogs with dexamethasone-resistant PDH. However, the percentage of dogs with PDH that show suppression at higher doses of dexamethasone is similar to that observed for the 0.1 mg/kg protocol.

# Endogenous Adrenocorticotropic Hormone Concentration

I do not routinely measure plasma ACTH concentrations because the LDDS test and abdominal ultrasound are very effective in differentiating between PDH and AT. I use plasma ACTH concentrations to provide clarity in confusing cases in which test results for hyperadrenocorticism and findings on abdominal ultrasound conflict (e.g., a dog with an adrenal mass but suppression on the LDDS test or a dog with an adrenal mass, enlargement of the contralateral adrenal gland, and lack of suppression on the LDDS test). Determination of a baseline plasma ACTH concentration is not used to diagnose hyperadrenocorticism because many of the concentrations in dogs with hyperadrenocorticism are within the reference range (2 to 25 pmol/L). However, determination of a single baseline plasma ACTH concentration may aid in distinguishing dogs with ATH from those with PDH once the diagnosis of hyperadrenocorticism is established. Adrenocortical tumors and iatrogenic hyperadrenocorticism should suppress ACTH secretion, and PDH is the result of excessive ACTH secretion (see Fig. 53-2). Approximately 60% of dogs with ATH have undetectable plasma ACTH concentrations, whereas 85% to 90% of dogs with PDH have plasma ACTH concentrations greater than 10 pmol/L and 35% have ACTH concentrations greater than 25 pmol/L. Plasma ACTH concentrations of 2 to 10 pmol/L are nondiagnostic. Several commercial veterinary endocrine laboratories perform endogenous ACTH assays for dogs. The laboratory should be consulted for information on sample collection and handling; results should be interpreted on the basis of the reference range established for the laboratory being used.

#### **Medical Treatment**

Medical options for treating hyperadrenocorticism are listed in Table 53-3. The most viable treatment options for dogs are mitotane and trilostane.

# **MITOTANE**

Chemotherapy using mitotane (0,0'DDD; Lysodren; Bristol Myers Oncology) is the most commonly used treatment for PDH and is a viable alternative to adrenalectomy for treatment of ATs causing hyperadrenocorticisim. There are two treatment protocols: the traditional approach, the goal of which is to control the hyperadrenal state without causing clinical signs of hypoadrenocorticism, and medical adrenalectomy, the goal of which is to destroy the adrenal cortex and create hypoadrenocorticism. I prefer the traditional approach initially and consider medical adrenalectomy in dogs that fail to respond to the traditional approach or that become non-responsive to mitotane after months or years of maintenance therapy.

# Traditional Approach to Mitotane Treatment

For the traditional approach, there are two phases of mitotane therapy: an initial induction phase designed to gain control of the disorder, and a lifelong maintenance phase designed to prevent recurrence of the signs of the disease.

TABLE 53-3

Drugs that Have Been Used to Treat Hyperadrenocorticism in Dogs

DRUG	MECHANISM OF ACTION	INDICATIONS	INITIAL DOSAGE	EFFICACY
Mitotane	Lysis of adrenal cortex	PDH, ATH	50 mg/kg divided q12h with food	>80%
Trilostane	Inhibition of cortisol biosynthesis	PDH, ATH	0.5 to 1.0 mg/kg q12h	~80%
Ketoconazole	Inhibition of cortisol biosynthesis	PDH, ATH	5 mg/kg q12h	<75%
Deprenyl	Inhibition of dopamine metabolism*	PDH	1 mg/kg q24h	<20%
Cyproheptadine	Serotonin antagonist†	PDH	_	<10%
Bromocriptine	Dopamine agonist	PDH	<del></del>	<10%

PDH, Pituitary-dependent hyperadrenocorticism; ATH, adrenal tumor causing hyperadrenocorticism.

<sup>\*</sup>CNS dopamine suppresses CRH and ACTH secretion.

<sup>†</sup> CNS serotonin stimulates CRH and ACTH secretion.

# **Induction Therapy**

The mitotane dosage during induction therapy is 40 to 50 mg/kg, divided into two doses. The daily dosage is reduced to 25 to 35 mg/kg in dogs without polydipsia or with concurrent diabetes mellitus. Gastrointestinal absorption of mitotane is enhanced in the presence of fat. Mitotane is more effective when each dose is ground up, mixed with a small amount of vegetable oil, and administered with food. Concurrent prednisone administration (0.25 mg/kg q24h) during induction therapy is a matter of personal preference. If prednisone is not used during induction therapy, it should always be dispensed before beginning induction therapy so that the client has glucocorticoids on hand should adverse reactions to mitotane develop.

The induction phase of mitotane treatment is typically done with the dog in the home environment. Client awareness of their dog's activity, mental awareness, appetite, water consumption, and overall well-being is imperative for success. The usual amount of food offered to the dog can be decreased by approximately 25% during the induction phase to ensure that the dog remains hungry. Clients are instructed to stop mitotane treatment and contact their veterinarian if they observe lethargy, inappetence, vomiting, weakness, decreased water intake, or any other change in their dog that does not seem right. The veterinarian or a technician should call the client every day, beginning with the second day of therapy, to check on the health of the dog. The induction phase of therapy is usually complete once any reduction in appetite is noted or once daily water consumption decreases into the normal range (i.e., 80 ml/kg or less). Control is confirmed with the ACTH stimulation test. The first ACTH stimulation test should be performed 5 to 7 days after starting induction therapy, even if clinical signs of hyperadrenocorticism persist. Dogs that have responded clinically to the medication (or if the client is not certain about response) should not receive further therapy until results of the ACTH stimulation test are known. Dogs that have not yet responded clinically should undergo an ACTH stimulation test but should also remain on daily mitotane therapy pending results of the ACTH stimulation test.

The goal of therapy is to achieve a post-ACTH serum cortisol concentration of 2 to 5  $\mu$ g/dl. Daily mitotane therapy and weekly ACTH stimulation tests should be continued until a post-ACTH serum cortisol concentration falls within the desired range or signs of hypocortisolism develop. In most dogs clinical signs resolve and a post-ACTH serum cortisol concentration of less than 5  $\mu$ g/dl is achieved within 5 to 10 days of the start of the daily administration of 40 to 50 mg of mitotane/kg. A small number of dogs respond in less than 5 days, and an equally small number of dogs show minimal improvement after 20 to 30 consecutive days of therapy

Reasons for a prolonged or poor response to mitotane treatment include inadequate dose, inadequate absorption from the gastrointestinal tract, concurrent administration of drugs (e.g., phenobarbital) that stimulate hepatic microsomal drug-metabolizing enzymes and could accelerate the

metabolism of mitotane and decrease its serum concentration, existence of an AT rather than PDH, and client compliance issues. The absorption of mitotane is improved if it is given with food, especially a fatty meal, and if the tablet is crushed, mixed with a small amount of vegetable oil, and mixed with food. Typically, dogs with AT are more resistant to the adrenocorticolytic effects of mitotane than dogs with PDH. If tests to differentiate PDH from AT were not performed, dogs that are shown to be resistant to therapy, defined as showing little or no reduction in the post-ACTH plasma cortisol concentration after 20 or more days of therapy, should undergo further evaluation (i.e., abdominal ultrasound) to determine whether an AT is an explanation for the resistance. Rarely, dogs with PDH require more than 30 consecutive days of mitotane therapy before the desired response is seen.

# **Maintenance Therapy**

Mitotane must be administered periodically to prevent recurrence of clinical signs. The maintenance phase of mitotane therapy should be initiated once the post-ACTH serum cortisol concentration is less than 5 µg/dl and the dog appears healthy. The maintenance dose is defined as the weekly amount of mitotane administered, regardless of whether the weekly dose is given once per week or divided into multiple doses and given on several days. Adverse reactions caused by sensitivity to the drug are less likely to occur when the weekly dose is divided and given on several days of the week. The typical initial weekly maintenance dosage of mitotane is 50 mg/kg administered orally, divided into two or three doses, and administered on 2 or 3 days of each week (e.g., Monday and Thursday or Monday, Wednesday, and Friday). The maintenance dose of mitotane is decreased from 50 mg/ kg/week to 25 mg/kg/week if the post-ACTH serum cortisol concentration is less than 2 µg/dl and the dog appears healthy. Mitotane treatment is discontinued and prednisone treatment initiated if the post-ACTH serum cortisol concentration is less than 2 µg/dl and the dog is exhibiting clinical signs of hypoadrenocorticism (i.e., lethargy, inappetence, vomiting).

The initial dose of lysodren during maintenance therapy is arbitrary, and subsequent adjustments are made on the basis of results of ACTH stimulation tests; the first test is performed 3 to 4 weeks after the start of maintenance therapy. The goal of maintenance therapy is to maintain the post-ACTH serum cortisol concentration between 2 and 5 µg/dl in an otherwise healthy dog. The dose and frequency of administration of mitotane are adjusted, as needed, to maintain a hypoadrenal response to ACTH administration. If the post-ACTH serum cortisol is between 2 and 5 µg/dl, a change in treatment is not indicated and the ACTH stimulation test should be repeated in 6 to 8 weeks. If the post-ACTH serum cortisol concentration is greater than 5 µg/dl, the amount of mitotane per administration or the frequency of administration is increased; if the post-ACTH serum cortisol concentration is less than 2 µg/dl, the mitotane dose or frequency of administration is decreased; mitotane therapy is temporarily discontinued if clinical signs of hypoadrenocorticism are present. An ACTH stimulation test is performed 3 to 4 weeks after changing the dose or frequency of administration of mitotane. Once the post-ACTH serum cortisol concentration is stable and in the range of 2 to 5 µg/dl, the ACTH stimulation test should be repeated every 3 to 6 months thereafter unless clinical signs of hyperadrenocorticism or hypoadrenocorticism develop. In most dogs an initially effective maintenance dose of mitotane becomes inadequate as the compensatory sustained increase in plasma ACTH concentration counters the adrenocorticolytic effects of mitotane. With time (i.e., months to years), the dose and frequency of administration of mitotane must usually be increased to compensate for this effect. Periodic ACTH stimulation testing will identify an increase in the post-ACTH serum cortisol concentration above 5 µg/dl, allowing the clinician to adjust the mitotane treatment protocol before clinical signs of hyperadrenocorticism develop and another round of induction therapy is needed. In some dogs this can ultimately necessitate daily mitotane administration, sometimes with poor control of the disorder. Alternative therapy (i.e., medical adrenalectomy using mitotane, trilostane) should be considered for dogs that become insensitive to mitotane

#### **Adverse Reactions to Mitotane Treatment**

Adverse reactions to mitotane treatment result from sensitivity to the drug or from excessive administration and the subsequent development of glucocorticoid and, if severe, mineralocorticoid deficiency (Box 53-4). The most common reactions to mitotane are gastric irritation and vomiting occurring shortly after its administration. If the gastric upset is the result of drug sensitivity and not hypoadrenocorticism, dividing the dose further, increasing the interval between administrations, or both can help minimize vomiting.

The excessive administration of mitotane results in clinical signs of hypocortisolism, including weakness, lethargy, anorexia, vomiting, and diarrhea. Clinical improvement is usually seen within hours of the administration of prednisone (0.25 to 0.5 mg/kg, administered orally). If the dog responds, the initial dosage of glucocorticoids should be continued for 3 to 5 days and then gradually decreased and stopped over the ensuing 1 to 2 weeks. Mitotane therapy should be stopped until the dog is normal when it is not receiving glucocorticoids. An ACTH stimulation test performed once the dog is healthy and not receiving glucocorticoids can help determine when to start mitotane treatment. Ideally, mitotane treatment should be started when the post-ACTH serum cortisol concentration is  $2 \mu g/dl$  or greater. The weekly dose of mitotane should be reduced when therapy is reinitiated.

Excessive administration of mitotane ultimately causes hypoaldosteronism. Mineralocorticoid deficiency should be considered in any dog with signs of hypocortisolism that does not respond to glucocorticoid therapy. Finding hyponatremia and hyperkalemia supports a diagnosis of hypoaldosteronism, and mineralocorticoid therapy is indicated in such dogs (see p. 840). Hypoaldosteronism can develop within

days of the start of mitotane therapy in some dogs. Hypoal-dosteronism can resolve and hyperadrenocorticism recur spontaneously, but this is unpredictable. Some dogs remain mineralocorticoid deficient for the remainder of their lives.

Mitotane may induce the development of neurologic signs, including stupor, head pressing, pacing, circling, seizures, ataxia, and blindness. Neurologic signs are usually transient, typically last 24 to 48 hours after mitotane administration, and usually occur in dogs that have been receiving the drug for more than 6 months. The primary differential diagnoses in such animals are pituitary macrotumor syndrome (see p. 814), hypoadrenocorticism, and thromboemboli. Adjustments in the dose or frequency of mitotane administration or temporary discontinuation of the therapy may alleviate the neurologic signs. An alternative mode of therapy should be considered if neurologic signs persist (discussed in more detail later).

# Management of Concurrent Diabetes Mellitus

Hyperadrenocorticism and diabetes mellitus are common concurrent diseases in dogs. Presumably, hyperadrenocorticism develops initially and subclinical diabetes mellitus becomes clinically apparent as a result of the insulin resistance caused by the hyperadrenal state. For most of these

dogs, glycemic control remains poor despite insulin therapy, and good glycemic control is generally not possible until the hyperadrenocorticism is controlled. Occasionally, diabetic dogs presumably in the early stages of hyperadrenocorticism (often identified while pursuing the cause for an increased ALP) will be responsive to insulin and have good control of glycemia. Because the diabetes is well controlled, the decision to treat or not treat the hyperadrenocorticism in these dogs should be based on other factors, such as the presence of additional clinical signs or physical examination findings and the clinician's index of suspicion for the disease. The clinician should adopt a wait-and-see approach in the absence of strong evidence for hyperadrenocorticism in these dogs. Poor control of the diabetic state will eventually occur if hyperadrenocorticism is present.

The initial focus should be on treating the hyperadrenal state in a poorly controlled diabetic dog diagnosed with hyperadrenocorticism. Insulin therapy is indicated during induction therapy; however, aggressive efforts to control the blood glucose concentration should not be attempted. Rather, a conservative dose (0.5 to 1.0 U/kg) of intermediate-acting insulin (i.e., lente or NPH) is administered twice a day to prevent ketoacidosis and severe hyperglycemia (blood glucose concentration greater than 500 mg/dl). Monitoring induction therapy in the hyperadrenal dog with concurrent diabetes mellitus is similar to that used for the hyperadrenal dog (see the section on monitoring induction therapy) with one exception. Monitoring water consumption is not reliable when concurrent diabetes mellitus is present because both diseases cause polyuria and polydipsia and because polyuria and polydipsia may persist if poor control of glycemia persists despite the fact that the hyperadrenocorticism is under control. As control of the hyperadrenocorticism is achieved, insulin antagonism caused by the hyperadrenocorticism resolves and tissue sensitivity to insulin improves. To help prevent hypoglycemic reactions, clients are asked to test urine for the presence of glucose, preferably two or three times each day. Any urine sample found to be negative for glucose should be followed by a 20% to 25% reduction in the insulin dose and performance of an ACTH stimulation test. Critical assessment of glycemic control and adjustments in insulin therapy, if indicated, should be initiated once hyperadrenocorticism is controlled and maintenance mitotane therapy initiated.

## Medical Adrenalectomy Using Mitotane

An alternative to the traditional mitotane treatment protocol is to intentionally cause complete destruction of the adrenal cortices by administering an excessive amount of mitotane. In theory, therapy for the ensuing adrenocortical insufficiency would then be necessary for the life of the dog. The protocol consists of administering mitotane at a dosage of 75 to 100 mg/kg daily for 25 consecutive days, given in three or four doses per day, with food, to minimize neurologic complications and ensure good intestinal absorption of the drug. Lifelong prednisone (0.1 to 0.5 mg/kg q12h initially) and mineralocorticoid (see p. 840) therapy is begun at the start of

mitotane administration. The prednisone dose is tapered after completion of the 25-day protocol. Unfortunately, relapse with signs of hyperadrenocorticism occurs within the first year alone in approximately 33% of dogs so treated, indicating the need for periodic ACTH stimulation testing similar to that done in animals treated with the traditional mode of therapy. In addition, this treatment can be considerably more expensive than long-term treatment with mitotane because of the expense of treating addisonian dogs. For these reasons, medical adrenalectomy is reserved for dogs that show a poor response to the traditional form of treatment.

#### **TRILOSTANE**

Trilostane (Vetoryl, Arnolds Veterinary Products) is a competitive inhibitor of 3-β-hydroxysteroid dehydrogenase, which mediates the conversion of pregnenolone to progesterone in the adrenal gland. The net effect is inhibition of cortisol production (Fig. 53-15). Trilostane is currently the preferred enzyme blocker for treating hyperadrenocorticism. The clinical efficacy of trilostane is excellent (approximately 80%), and trilostane can control clinical signs of hyperadrenocorticism in dogs for prolonged periods of time (longer than 1 year). Trilostane is used as the primary treatment modality for PDH in dogs, as an alternative in dogs in which mitotane is ineffective or not usable because of problems with drug sensitivity, and as a way to reverse the metabolic derangements of hyperadrenocorticism before adrenalectomy. Trilostane is currently available as 30-, 60-, and 120mg capsules. Compounding of capsules to different strengths (e.g., 10 or 20 mg) may be required. The published initial treatment protocol is 30 mg once a day for dogs weighing less than 5 kg, 60 mg once a day for dogs weighing 5 to 20 kg, 120 mg once a day for dogs weighing 20 to 40 kg, and 180 mg once a day for dogs weighing more than 40 kg. However, in our experience, twice-daily dosing using a lower dose provides better control than once-daily dosing using the aforementioned dosing schedule and the occurrence and severity of adverse reactions are less frequent. Our approach is to begin treatment using a trilostane dosage between 0.5 and 1 mg/kg twice daily.

The dosage and frequency of administration of trilostane are adjusted, as needed, until clinical signs are controlled. An ACTH stimulation test and serum electrolytes should be performed 10 to 14 days after initiation of treatment and 4 to 6 hours after trilostane administration. In addition, the client should bring in a urine sample collected at home the morning of the ACTH stimulation test for a UCCR. The goals of therapy are the same as those of mitotane therapy: clinical improvement without the development of illness, lack of an adrenocortical response to ACTH, and a normal UCCR. Results of the ACTH stimulation test are used to adjust the dosage of trilostane; the goal is a post-ACTH cortisol concentration between 2 and 5 µg/dl. The UCCR is used to determine frequency of trilostane administration in dogs receiving the drug once daily. If clinical signs persist, results of the ACTH stimulation test are indicative of control of the disease, and the UCCR is increased, then the frequency

#### FIG 53-15

Steroid biosynthetic pathways in the adrenal cortex. The branching pathways for glucocorticoids, mineralocorticoids, and adrenal androgens are shown. The site of blockade in the steroid biosynthetic pathways by the enzyme inhibitors trilostane (T), ketoconazole (K), metyrapone (M), and aminoglutethimide (A) are also shown.

of trilostane administration should be increased to twice a day. Serum electrolytes are monitored for changes consistent with the onset of hypoaldosteronism. Once control of the hyperadrenal state is attained, an ACTH stimulation test, serum electrolytes, and UCCR should be evaluated every 3 to 4 months.

Adverse effects of trilostane include lethargy, vomiting, and electrolyte shifts compatible with hypoadrenocorticism. Permanent hypoadrenocorticism has been reported in a small number of dogs. Histopathologic examination of the adrenal gland in dogs treated with trilostane has revealed adrenocortical necrosis of variable severity in some dogs—findings that, if severe, could explain persistent hypoadrenocorticism in affected dogs. Acute death has been reported in a small number of dogs shortly after the initiation of trilostane treatment.

#### KETOCONAZOLE

Ketoconazole reversibly inhibits adrenal steroidogenesis (see Fig. 53-15). The initial dosage of ketoconazole is 5 mg/kg q12h, and subsequent increases in the dosage are based on results of an ACTH stimulation test performed 10 to 14 days later and while the dog is still receiving ketoconazole. The goals of therapy are similar to those discussed for trilostane. Approximately 20% to 25% of dogs do not respond to the drug as a result of poor intestinal absorption. Adverse reactions are primarily a result of hypocortisolism and include lethargy, inappetence, vomiting, and diarrhea. Unfortunately, it is difficult to control the clinical signs of hyperadrenocorticism without creating problems with hypocortisolism.

## L-DEPRENYL

L-Deprenyl (Anipryl, Deprenyl Animal Health) inhibits dopamine metabolism and increases hypothalamic and pituitary concentrations of dopamine, which in turn inhibits corticotropin-releasing hormone (CRH) and ACTH secretion. The current dosage recommendation for L-Deprenyl is 1 mg/kg once daily initially, with an increase to 2 mg/kg once daily if there is no response after 2 months. The efficacy of

this drug for the treatment of PDH is, at best, 20%. The vast majority of dogs with PDH have a pituitary tumor, not alterations in neurotransmitter control of hypothalamic-pituitary gland function. Concentrations of an endogenous amphetamine, phenylethylamine, increase in the brains of dogs treated with L-Deprenyl, which may improve the dog's level of activity and its interactions with family members independent of any improvement in the hyperadrenal state.

## **ADRENALECTOMY**

Adrenalectomy is the treatment of choice for an AT unless metastatic lesions or invasion of surrounding organs or blood vessels is identified during the preoperative evaluation; the dog is considered a poor anesthetic risk because it has a concurrent disease (e.g., heart failure) or is debilitated as a result of its hyperadrenal state; or the probability of perioperative thromboembolism is considered high because of systemic hypertension, an increased urine protein: creatinine ratio, or a decreased serum antithrombin III concentration. The probability of successful adrenalectomy is lower and the likelihood of perioperative complications is greater the larger the adrenal mass. Removal of an adrenal mass that has a diameter in excess of 6 cm can be difficult even when the surgery is performed by an experienced surgeon. The larger the adrenal mass, the greater the probability that the adrenal mass is a carcinoma and that metastasis has occurred, regardless of findings during the preoperative evaluation. Treatment with mitotane or trilostane offers a viable alternative to adrenalectomy, especially for aged dogs or dogs at increased risk for anesthetic, surgical, or postsurgical problems. (See Suggested Readings for detailed information on surgical techniques.)

The most worrisome complication of adrenalectomy is thromboembolism, which typically develops during or within 72 hours of surgery and carries a high mortality rate (see p. 814). Several steps help minimize this complication. Trilostane treatment for 3 to 4 weeks before surgery can reverse the metabolic derangements of hyperadrenocorticism and minimize many of the complications associated with adrenalectomy. Plasma is a source of antithrombin III and should be administered during surgery. Heparin or other anticoagulant therapy should be administered during and for several days after adrenalectomy (see Chapter 12). Dogs should go for frequent short walks within hours of the surgery to promote blood flow and minimize clot formation. Anesthetic drugs and pain medications should be administered at dosages that allow the dog to be ambulatory within 4 hours of the surgery. Despite these measures, thromboembolism remains a common perioperative complication that should be thoroughly discussed with clients who are considering adrenalectomy.

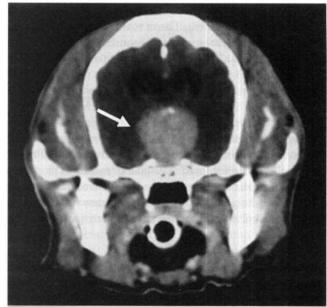

Glucocorticoid therapy is not indicated before adrenalectomy because it may worsen hypertension, cause overhydration, and increase the risk of thromboembolic episodes. Beginning with anesthesia, IV fluids should be administered at a surgical maintenance rate. Acute hypocortisolism uniformly occurs after adrenalectomy. After the surgeon identi-

fies the adrenal tumor, dexamethasone (0.05 to 0.1 mg/kg) should be placed in the IV infusion bottle. This dose should be given over a 6-hour period. A tapering dose (e.g., decreasing the dose by 0.02 mg/kg/24 h) of dexamethasone should continue to be administered intravenously at 12-hour intervals until the dog can safely be given oral medication without the danger of vomiting (typically 24 to 72 hours postoperatively). At that point, the glucocorticoid supplement should be switched to oral prednisone (0.25 to 0.5 mg/kg q12h). Once the dog is eating and drinking on its own, the frequency of prednisone administration should be decreased to once a day and given in the morning. The prednisone dosage is then gradually reduced during the ensuing 3 to 4 months. If a unilateral adrenalectomy has been performed, prednisone supplementation can eventually be discontinued once the contralateral normal adrenocortical tissue becomes functional. Lifelong prednisone at a dosage of 0.1 to 0.2 mg/ kg administered once or twice daily is usually required for dogs that undergo bilateral adrenalectomy.

Serum electrolyte concentrations should be closely monitored postoperatively. Development of mild hyponatremia and hyperkalemia is common within 72 hours of surgery and usually resolves in a day or two as exogenous glucocorticoid doses are reduced and the dog begins to eat. Mineralocortioid treatment is recommended if the serum sodium concentration decreases to less than 135 mEq/L or serum potassium concentration increases to greater than 6.5 mEq/ L. An injection of desoxycorticosterone pivalate (DOCP; Percorten-V; Novartis Pharmaceuticals) is recommended, with measurement of serum electrolytes performed 25 days after the injection (see p. 840). If the dog is healthy and serum electrolytes are normal on day 25, the dog should be reevaluated 7 days later. If serum electrolytes are still normal, additional DOCP treatment is not needed. If hyponatremia or hyperkalemia is identified on day 25, another injection of DOCP should be administered but with the dosage reduced by 50% and serum electrolytes evaluated 25 days later.

#### RADIATION THERAPY

Approximately 50% of dogs have a pituitary mass identified on CT or MRI at the time PDH is diagnosed. In approximately 50% of these dogs, the pituitary mass grows over the ensuing 1 to 2 years, eventually causing pituitary macrotumor syndrome (see p. 814). Pituitary macroadenoma is tentatively diagnosed by ruling out other causes of the neurologic disturbances and is confirmed by CT or MRI findings (see Fig. 53-4). Development of neurologic signs from a pituitary macrotumor is a common reason for clients to request euthanasia of dogs with PDH. Irradiation has successfully reduced the tumor size and lessened or eliminated neurologic signs in dogs with pituitary macrotumor syndrome (Fig. 53-16). The primary mode of radiation treatment is cobalt 60 photon irradiation or linear accelerator photon irradiation. Treatment usually involves the delivery of a predetermined total dose of radiation given in fractions over a period of several weeks. Currently a total dose of 48 Gy, given in 4 Gy doses 3 to 5 days per week for 3 to 4 weeks, is typi-

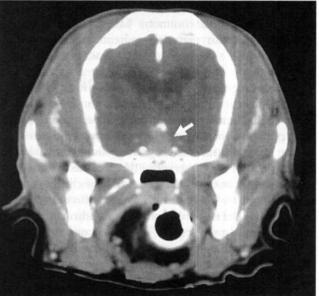

FIG 53-16

**A**, Computed tomography (CT) image of the pituitary region of a 9-year-old, female spayed Cocker Spaniel with pituitary-dependent hyperadrenocorticism (PDH). The PDH had been treated with mitotane for 2 years, at which time the dog developed lethargy, inappetence, and weight loss. A large mass measuring approximately 2.0 cm in diameter is evident in the hypothalamic-pituitary region (arrow). **B**, CT image of the pituitary region 18 months after completion of radiation therapy. The volume of the mass decreased by approximately 75%, compared with the volume before treatment. Clinical signs related to the pituitary macrotumor resolved, and mitotane treatment was discontinued after radiation treatment.

cally administered to hyperadrenal dogs with pituitary macroadenoma at our hospital.

Prognostic factors that affect survival time after radiation therapy include the severity of neurologic signs and the relative size of the tumor. Generally, dogs with subtle or mild В

neurologic clinical signs and the smallest tumors show the best response to treatment. Theon et al. (1998) found a mean survival time after radiation of 25 months in dogs with mild neurologic signs, 17 months in dogs with severe neurologic signs, and only 5 months in untreated dogs with neurologic signs. Because of the high prevalence of a pituitary mass at the time PDH is diagnosed and the potential for future growth and development of neurologic signs, examination of the pituitary gland using CT or MRI and radiation therapy if a mass is identified should be discussed with the client at the time PDH is diagnosed. The goal of radiation therapy is to shrink the mass and prevent development of macrotumor syndrome; mitotane or trilostane therapy may still be needed to control clinical signs of hyperadrenocorticism.

# **Prognosis**

The average life expectancy in dogs with adrenal-dependent hyperadrenocorticism that survive the initial postadrenalectomy month is approximately 36 months. Dogs with adrenocortical adenoma and adrenocortical carcinoma that has not metastasized (uncommon) have a good prognosis, whereas dogs with metastatic adrenocortical carcinoma (common) have a poor prognosis, with these dogs typically succumbing to the disease within a year of diagnosis. Although clinical signs can be controlled with trilostane and mitotane, death ultimately results from the debilitating effects of the tumor, complications of hyperadrenocorticism (e.g., pulmonary thromboembolism), or other geriatric disorders (e.g., renal insufficiency, congestive heart failure).

The prognosis for dogs with PDH depends in part on the age and overall health of the dog and on the client's commitment to therapy. The mean life span of affected dogs after diagnosis of PDH is approximately 30 months. Younger dogs may live considerably longer (i.e., 5 years or longer). Many dogs ultimately die or are euthanized because of complications related to hyperadrenocorticism (e.g., pituitary macrotumor syndrome) or other geriatric disorders.

# ATYPICAL CUSHING'S SYNDROME IN DOGS

Dogs with atypical Cushing's syndrome have clinical features suggestive of hyperadrenocorticism but persistently normal or equivocal endocrine test results. An imbalance of one or more of the adrenocortical steroid hormone intermediates required for synthesis of cortisol (see Fig. 53-15) is believed to be the cause. It has been hypothesized that a relative deficiency in enzymes required for cortisol synthesis (such as 21- $\beta$ -hydroxylase or 11- $\beta$ -hydroxylase) cause accumulation of steroid precursors proximal to the blockade in the synthetic pathway. High concentrations of one or more steroid precursors may cause clinical signs or may be shunted into alternative metabolic pathways and cause excesses in other steroid hormones, such as androstenedione. Increased serum adrenocortical steroid hormone intermediates often occur in conjunction with cortisol in dogs with PDH and cortisol-

secreting ATs. In contrast, dogs with atypical Cushing's syndrome have normal or inconclusive serum cortisol concentrations and an increase in one or more adrenocortical steroid hormone intermediates, most notably 17-hydroxy-progesterone.

Adrenal tumors that secrete progesterone and 17-hydroxyprogesterone cause a clinical syndrome that mimics hyperadrenocorticism in dogs and cats. Clinical signs presumably result from intrinsic glucocorticoid activity of progestins, progestin-induced displacement of cortisol from cortisolbinding protein in the circulation, or both. An atypical form of PDH has also been described in which clinical features mimic hyperadrenocorticism, abdominal ultrasound reveals adrenal glands that are normal or mildly increased in size, tests of the pituitary-adrenocortical axis are normal or inconclusive, pre- and post-ACTH serum 17-hydroxyprogesterone concentrations are increased, and clinical signs improve with mitotane treatment. Diagnosis requires evaluation of serum and plasma adrenocortical steroid hormone intermediates and sex hormones before and 1 hour after the IV administration of 5 μg/kg of synthetic ACTH (Cosyntropin). The most common abnormality is an increase in serum 17-hydroxyprogesterone concentration. Currently, the only laboratory with established normal values for precursor and sex steroids is the Endocrinology Laboratory at the University of Tennessee, College of Veterinary Medicine, Knoxville, TN 37901-1071. Treatment recommendations have included low dosages of mitotane (10 mg/kg/day initially) and trilostane, although Sieber-Ruckstuhl et al. (2006) failed to document a decrease in 17-hydroxyprogesterone concentrations in dogs with PDH treated with trilostane.

I do not routinely measure serum adrenocortical steroid hormone intermediates or sex hormones when initially evaluating dogs for hyperadrenocorticism. I reserve measurement of these hormones for those dogs with clinical features suggestive of hyperadrenocorticism but persistently normal or equivocal test results for hyperadrenocorticism.

## HYPERADRENOCORTICISM IN CATS

Hyperadrenocorticism is uncommon in cats. Although many of the clinical characteristics of feline hyperadrenocorticism are similar to those seen in dogs, there are some important differences that should be emphasized. Most notable is the very strong association with diabetes mellitus; the progressive, relentless weight loss leading to cachexia; and dermal and epidermal atrophy leading to extremely fragile, thin, easily torn and ulcerated skin (i.e., feline fragile skin syndrome) in cats with hyperadrenocorticism. Establishing the diagnosis can be difficult, and effective medical treatment for hyperadrenocorticism in cats has yet to be identified.

# Etiology

Hyperadrenocorticism in cats is classified as either pituitary dependent (PDH) or adrenocortical tumor dependent (ATH). Approximately 80% of cats with hyperadrenocorti-

cism have PDH and 20% have ATH, with 50% of ATHs being adenomas and 50% carcinomas. Cats with PDH have a pituitary microadenoma, macroadenoma, or carcinoma identified at necropsy. Iatrogenic hyperadrenocorticism is uncommon in cats and typically takes months of prednisone or prednisolone administration before clinical signs occur.

#### **Clinical Features**

# CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

Hyperadrenocorticism is a disease of older (average age 10 years) mixed-breed cats. There is a strong correlation between hyperadrenocorticism and diabetes mellitus, and the most common initial clinical signs of feline hyperadrenocorticism (i.e., polyuria, polydipsia, polyphagia) are more likely caused by diabetes than by hyperadrenocorticism. Other clinical signs and physical examination findings are not as frequently observed in cats as in dogs and tend to be very subtle in the early stages of the disease (Box 53-5; Fig. 53-17).

A frequent clue to the existence of hyperadrenocorticism in cats is the presence of diabetes mellitus that is difficult to control and ultimately progresses to severe insulin resistance. Initially, clinical signs of hyperadrenocorticism are mild and tests of the pituitary-adrenocortical axis are often inconclusive and difficult to interpret in the presence of poorly controlled diabetes. With time, hyperadrenocorticism becomes more apparent as affected cats become progressively more debilitated despite aggressive insulin therapy; weight loss leads to cachexia; and dermal and epidermal atrophy result in extremely fragile, thin, easily torn, and ulcerated skin (Fig. 53-18). Dermal and epidermal lesions often occur when the cat is groomed or when the cat is handled during the physical examination. Insulin resistance is usually quite severe by

the time cachexia and skin fragility develop. The primary differential diagnosis for insulin resistance, cachexia, and feline fragile skin syndrome is excess progestins such as that which occurs with progesterone-secreting adrenal tumors (see p. 844).

# **CLINICAL PATHOLOGY**

The classic clinicopathologic alterations seen in dogs with hyperadrenocorticism are infrequently found in cats. The most frequently observed abnormalities in cats are hyperglycemia, glycosuria, hypercholesterolemia, and a mild increase in alanine aminotransferase activity. These alterations can be explained by concurrent, poorly regulated diabetes mellitus. A stress leukogram, an increase in ALP activity, and isosthenuric-hyposthenuric urine are not common findings in hyperadrenal cats. An inability to document histologic changes in the liver consistent with steroid-induced hepatopathy, an absence of the steroid-induced alkaline phosphatase isoenzyme activity, and the relatively short half-life of ALP activity in cats may account for the absence of an observed increase in ALP activity. Urine abnormalities frequently identified in dogs with hyperadrenocorticism are not common in cats.

#### DIAGNOSTIC IMAGING

Abdominal ultrasonography is used to identify adrenal masses and to clarify the clinician's index of suspicion for PDH. The interpretation of results of adrenal imaging in cats is similar to that in dogs (see p. 815). The maximum width of the adrenal gland in healthy cats is typically less than 0.5 cm. Adrenomegaly should be suspected when the maximum width is greater than 0.5 cm; a maximum width greater than 0.8 cm is strongly suggestive of adrenomegaly. The finding of easily visualized, bilaterally large adrenals in a cat with appropriate clinical signs, physical examination findings, and abnormal test results of the pituitary-adrenocortical axis is strong evidence for PDH. CT and MRI can be used to look for pituitary macroadenoma and to assess the size of an adrenal mass and extent of infiltration of the mass into surrounding blood vessels and organs before adrenalectomy.

# TESTS OF THE PITUITARY-ADRENOCORTICAL AXIS

Although the tests used to diagnose hyperadrenocorticism in cats and dogs are similar (see p. 818), there are some important differences in the testing protocol and in the interpretation of results (Table 53-4). I rely most heavily on the UCCR, dexamethasone suppression test, and abdominal ultrasonography to establish the diagnosis of hyperadrenocorticism in cats. The ACTH stimulation test lacks sensitivity in the cat and is not recommended. I also rely on abdominal ultrasound rather than endogenous plasma ACTH concentration to differentiate PDH from ATH.

#### **Urine Cortisal/Creatinine Ratio**

The theory behind and the specifics regarding the UCCR are similar for dogs and cats and discussed on p. 819. The cat

<sup>\*</sup> Common.

A and B, A 9-year-old cat with pituitary-dependent hyperadrenocorticism (PDH) and insulin-resistant diabetes mellitus. Note the relatively normal physical appearance of the cat in its normal posture (A). Abdominal enlargement and inguinal alopecia are evident on physical examination (B). C and D, A 16-year-old cat with PDH and insulin-resistant diabetes mellitus. Note the relatively normal appearance of the cat and the alopecia and ulceration in the dorsal cervical and anterior thoracic region in the area of a collar worn by the cat. Alopecia was also present in the ventral region of the neck.

reference range for the UCCR performed on urine collected at home is less than  $3.6 \times 10^{-5}$  (often listed as less than 36); this value may vary among laboratories. I use the UCCR as the initial screening test for hyperadrenocorticism in cats. A normal UCCR is a strong finding against the diagnosis; an increased ratio does not establish the diagnosis by itself but supports performing the dexamethasone suppression test.

## **Dexamethasone Suppression Test**

The duration of the suppressive effects of intravenously administered dexamethasone on serum cortisol concentrations is more variable in cats than dogs. Approximately 20% of healthy cats do not experience the suppressive effects of dexamethasone, and their serum cortisol concentrations are greater than 1.4 ug/dl 8 hours after dexamethasone administration. This "escape phenomenon" is more likely to occur in cats receiving lower doses of dexamethasone. Because of potential misinterpretation caused by the escape phenome-

non and the fragile state of many diabetic hyperadrenal cats, I typically use only one dexamethasone suppression test protocol (0.1 mg/kg dexamethasone administered intravenously; blood obtained before and 4 and 8 hours after dexamethasone administration) when evaluating the pituitary-adrenocortical axis in cats. An 8-hour postdexamethasone serum cortisol concentration less than 1.0 ug/dl is suggestive of a normal pituitary-adrenocortical axis, values between 1.0 and 1.4 ug/dl are inconclusive, and values greater than 1.4 Jg/dl are supportive of the diagnosis of hyperadrenocorticism. The higher the 8-hour post-dexamethsone serum cortisol concentration above 1.4 ug/dl, the more supportive the test is for the diagnosis of hyperadrenocorticism. Similarly, a serum cortisol concentration greater than 1.4 µg/dl at the 4-hour postdexamethasone blood sampling time adds further support for the diagnosis of hyperadrenocorticism (Fig. 53-19). Whenever the 4-hour post-dexamethasone cortisol value is less than 1.4 ug/dl (especially less than 1.0 ug/

#### FIG 53-18

**A,** A 15-year-old cat with pituitary-dependent hyperadrenocorticism (PDH), insulin-resistant diabetes mellitus, and feline fragile skin syndrome. Note the torn skin over the back of the neck that occurred while the cat was being restrained during a physical examination. **B,** A 12-year-old cat with hyperadrenocorticism and severe insulin-resistant diabetes mellitus. This cat weighed 2.2 kg and was receiving 25 units of regular insulin three times a day with no glucose-lowering effect. Note the emaciated appearance, presumably resulting from protracted poor glycemic control, alopecia, severe dermal and epidermal atrophy, and lesions resulting from easily torn skin (arrow). **C,** A 17-year-old cat with PDH and insulin-resistant diabetes mellitus. Note the emaciated appearance of the cat, the enlarged abdomen (pot-belly appearance), and absence of hair growth on the ventral abdomen, which had been shaved for an abdominal ultrasound 10 months before presentation.

dl), the test results should be considered consistent with, but not definitively diagnostic of, hyperadrenocorticism and the clinician must rely on the clinical signs, physical examination findings, and results of other diagnostic tests to help establish the diagnosis. Results of the dexamethasone suppression test should never constitute the sole evidence for hyperadrenocorticism in cats.

# Adrenocorticotropic Hormone Stimulation Test

The peak increase in the post-ACTH serum cortisol concentration occurs earlier in cats than in dogs, and serum cortisol concentrations can approach baseline values by 1 or 2 hours

after the administration of synthetic or porcine ACTH, respectively. Whenever porcine ACTH gel is used, blood samples for cortisol determination should be obtained 1 and 2 hours after its administration. Whenever synthetic ACTH is used, blood samples should be obtained 30 minutes and 1 hour after its administration. The reference range for peak post-ACTH serum cortisol concentration is 5 to 15 µg/dl. Post-ACTH serum cortisol concentrations greater than 15 µg/dl are suggestive of hyperadrenocorticism. The sensitivity of the ACTH stimulation test in identifying hyperadrenocorticism is low in cats. Fewer than 50% of cats with hyperadrenocorticism confirmed at necropsy have abnormal ACTH stimulation test results consistent with the disease.

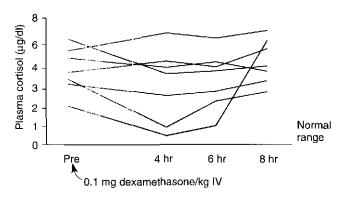

**TABLE 53-4** 

# Diagnostic Tests to Assess the Pituitary-Adrenocortical Axis in Cats with Suspected Hyperadrenocorticism

TEST	PURPOSE	PROTOCOL	RESULTS	INTERPRETATION
Urine cortisol: creatinine ratio	Rule out Cushing's syndrome	Urine collected at home	Normal	Not supportive of Cushing's syndrome
	•,		Increased	Additional tests for Cushing's indicated
			8-hr post-dexamethasone:	
Dexamethasone	Diagnose Cushing's	0.1 mg dexamethasone/kg IV;	<1.0 μg/dl	Normal
suppression test	syndrome	serum pre- and 4 and 8 hr post-dexamethasone	1.0-1.5 μg/dl	Nondiagnostic
			>1.5 µg/dl and	Suggestive†
			4 hr <1.5 μg/dl	Strongly
			>1.5 μg/dl and	suggestive‡
			4 hr >1.5 μg/dl	
				risol concentration:
ACTH stimulation	Diagnose Cushing's	2.2 IU of ACTH gel*/kg IM;	>20 μg/dl	Strongly suggestive
	syndrome	serum pre- and 1 and 2 hrs	15-20 μg/dl	Suggestive
		post-ACTH or 0.125 mg of	5-15 μg/dl	Normal
		synthetic ACTH*/cat IM; serum pre- and 30 and 60 min post-ACTH	<5 μg/dl	latrogenic Cushing's syndrome
Endogenous ACTH	Differentiate	Plasma sample obtained	<2 pmol/L	ATH
	PDH from ATH	between 8 and 10 AM	2-10 pmol/L	Nondiagnostic
		Special handling required	>10 pmol/L	PDH

ACTH, Adrenocorticotropic hormone; IM, intramuscular; PDH, pituitary-dependent hyperadrenocorticism; ATH, adrenal tumor causing hyperadrenocorticism.

<sup>‡</sup>Strongly suggestive of hyperadrenocorticism.

# FIG 53-19

Dexamethasone suppression test results in seven cats with histologically confirmed hyperadrenocorticism. Blood for the cortisol determination was drawn before and 4, 6, and 8 hours after the intravenous administration of 0.1 mg of dexamethasone/kg body weight. In most cats the plasma cortisol concentration remained more than 1.4  $\mu$ g/dl throughout the test—results that are very consistent with a diagnosis of hyperadrenocorticism.

# Endogenous Plasma Adrenocorticotropic Hormone Concentration

The endogenous plasma ACTH concentration test is discussed on p. 824. The reference range for baseline plasma ACTH concentrations in cats is 2 to 13 pmol/l. Undetectable plasma endogenous ACTH concentrations (less than 2 pmol/L) are consistent with ATH, endogenous ACTH concentrations greater than 10 pmol/l are consistent with PDH, and endogenous ACTH concentrations between 2 and 10 are nondiagnostic.

# Diagnosis

Hyperadrenocorticism is diagnosed on the basis of history; findings on physical examination; results of routine blood and urine tests, abdominal ultrasonography, and tests of the pituitary-adrenocortical axis; and the clinician's index of suspicion for the disease. Ideally, all diagnostic tests performed in the assessment of a cat with suspected hyperadrenocorticism should be abnormal. Discordant test results raise doubt regarding the diagnosis. False-positive and false-negative results occur with all of the diagnostic tests used to assess the pituitary-adrenocortical axis. Although normal UCCR and dexamethasone suppression test results are inconsistent with a diagnosis of hyperadrenocorticism,

<sup>\*</sup>ACTH gel: Acthar Gel, Questcor Pharmaceuticals; Synthetic ACTH: Cortrosyn, Amphastar Pharmaceuticals.

<sup>†</sup> Suggestive of hyperadrenocorticism.

abnormal results of these tests do not by themselves confirm the diagnosis. If there is doubt or uncertainty about the diagnosis, therapy for hyperadrenocorticism should be withheld and the cat reevaluated 1 to 2 months later.

#### **Treatment**

Treatment of hyperadrenocorticism is problematic in cats, primarily because a reliable medical treatment for PDH has not been identified. Trilostane is the current treatment of choice because other treatments, such as mitotane, ketoconazole, and the enzyme inhibitor metyrapone, are ineffective or only transiently effective. The trilostane treatment and monitoring protocols are similar for dogs and cats (see p. 827). The initial dose is 1 to 2 mg/kg of body weight once daily. Adjustments in the dose and frequency of administration are based on clinical response and results of the ACTH stimulation test, UCCR, and serum electrolyte concentrations. In general, twice-daily dosing provides better control than once-daily dosing and should be the initial adjustment

in cats that remain symptomatic at the starting dose given once daily. In one study by Neiger et al. (2004), three cats with PDH were still alive 6, 11, and 20 months after starting trilostane therapy at 30 mg/cat once a day.

Aminoglutethimide (Cytadren, 30 mg/cat, administered orally q12h; Ciba-Geigy Pharmaceuticals) inhibits the conversion of cholesterol to pregnenolone, thereby reducing cortisol hypersecretion. Aminoglutethimide has been used successfully in controlling clinical signs of hyperadrenocorticism and hyperprogesteronemia in cats with progesterone-secreting tumors (Fig. 53-20) and appears to maintain its efficacy for a relatively prolonged period of time (i.e., months). Cobalt irradiation may be tried in cats with pituitary macrotumor, although clinical signs of hypercortisolemia may persist despite shrinkage of the tumor.

Adrenalectomy is the treatment of choice for ATH, and bilateral adrenolectomy is also an effective treatment for PDH. Medical treatment with trilostane is usually necessary for 4 to 6 weeks before adrenalectomy to reverse the catabolic

#### FIG 53-20

**A**, A 9-year-old male castrated domestic long-haired cat with a 2-year history of poorly controlled diabetes mellitus, failure of hair to regrow after clipping 1 year before presentation, and recent development of feline fragile skin syndrome. Diagnostic evaluation revealed an adrenocortical tumor, increased serum progesterone concentration, and suppression of the pituitary-adrenocortical axis on adrenocorticotropic hormone stimulation and dexamethasone suppression testing. A progesterone-secreting adrenocortical tumor was suspected. **B**, Five weeks after initiating treatment with aminoglutethemide. Feline fragile skin syndrome was resolving, hair was growing, and gynecomastia had developed. The serum progesterone concentration had decreased from a pretreatment value of 4.7 ng/ml to less than 1 ng/ml. **C**, Four months after adrenalectomy. Insulin-requiring diabetes mellitus had resolved.

state of the cat, improve skin fragility and wound healing, and decrease the potential for perioperative complications. The surgical approach and medical management during and after surgery are similar to those used in dogs (see p. 828). Treatment for hypoadrenocorticism should begin immediately after bilateral adrenalectomy and include injectable desoxycorticosterone pivalate (DOCP, 2.2 mg/kg, administered subcutaneously every 25 days initially; Percoten-V; Novartis Pharmaceuticals) or fludrocortisone acetate (Florinef, 0.05 mg/cat, administered orally q12h initially; ER Squibb & Sons) and prednisolone (1.0 to 2.5 mg once daily). Subsequent adjustments in the dose of DOCP or fludrocortisone acetate should be based on periodically measured serum electrolyte concentrations (see p. 840). Insulin therapy can be discontinued in approximately 50% of cats once hyperadrenocorticism is eliminated, and diabetes is easier to control using less insulin in the remaining cats.

# **Prognosis**

The prognosis is guarded to poor. Untreated hyperadrenal cats die within months after the diagnosis has been established because of the deleterious effects of chronic hypercortisolism and insulin-resistant diabetes mellitus on skin integrity and on immune and cardiovascular function and as a result of progressive weight loss leading to severe cachexia. The effectiveness of trilostane remains to be determined. Unilateral (ATH) or bilateral (PDH) adrenalectomy has the potential for excellent success; however, success depends, in part, on correction of the debilitated state and skin fragility with medical treatment before surgery, involvement of a surgeon with expertise in adrenal surgery, avoidance of perioperative complications, and the client's commitment to managing the iatrogenic adrenal insufficiency after bilateral adrenalectomy. Periodic evaluation of serum electrolytes and review of the treatment protocol are important. An addisonian crisis occurred months after surgery in several cats treated in our clinic and was believed to be responsible for the death of some.

# **HYPOADRENOCORTICISM**

# Etiology

Hypoadrenocorticism is a deficiency of mineralocorticoids, glucocorticoids, or both. Primary adrenocortical insufficiency (Addison's disease) involving a deficiency of both mineralocorticoid and glucocorticoid secretion is the most common. The etiology of primary hypoadrenocorticism is usually classified as idiopathic because the cause of the disease is not obvious and necropsies are usually done years after the diagnosis is established, at which time idiopathic atrophy of all layers of the adrenal cortex is the most frequent histopathologic finding. Immune-mediated destruction of the adrenal cortices is believed to occur in most dogs and cats with idiopathic adrenal insufficiency; lymphocytes, plasma cells, and fibrosis are common findings in animals that undergo necropsy near the time of diagnosis. Bilateral destruction of the

adrenal cortex by neoplasia (e.g., lymphoma), granulomatous disease, hemorrhagic infarction, arterial thrombosis, or drugs such as mitotane and trilostane can also cause primary adrenocortical insufficiency. For clinical signs to develop, it is believed that at least 90% of the adrenal cortices must be destroyed. The zones of the adrenal cortices are usually damaged at about the same rate, with aldosterone and glucocorticoid deficiency typically occurring in tandem. Destruction is progressive, ultimately leading to complete loss of adrenocortical function. Dogs and cats typically have complete loss of adrenocortical function at the time hypoadrenocorticism is diagnosed. A partial deficiency syndrome characterized by inadequate adrenal reserve may occur initially, with clinical signs manifested only during times of stress such as boarding, travel, and surgery. As destruction of the adrenal cortex progresses, hormone secretion becomes inadequate even under nonstressful conditions and a true metabolic crisis occurs without any obvious inciting event.

Mineralocorticoids (i.e., aldosterone) control sodium, potassium, and water homeostasis. In the setting of primary adrenocortical insufficiency, a loss of aldosterone secretion results in impaired renal conservation of sodium and chloride and the excretion of potassium, leading to the development of hyponatremia, hypochloremia, and hyperkalemia. The inability to retain sodium and chloride reduces extracellular fluid volume, leading to progressive development of hypovolemia, hypotension, a reduced cardiac output, and decreased perfusion of the kidneys and other tissues. Hyperkalemia has a deleterious effect on cardiac function, causing decreased myocardial excitability, an increased myocardial refractory period, and slowed conduction. A concurrent glucocorticoid deficiency typically results in gastrointestinal tract signs (e.g., anorexia, vomiting, diarrhea, weight loss) and changes in mental status (e.g., lethargy). One of the hallmark signs of hypocortisolism is impaired tolerance to stress, and clinical signs often become more pronounced when the animal is placed in stressful situations.

Some dogs and cats with hypoadrenocorticism present to the veterinarian with clinical signs of glucocorticoid deficiency but serum electrolyte concentrations that are within the reference range at initial presentation. A deficiency in glucocorticoid but not mineralocorticoid secretion is referred to as atypical hypoadrenocorticism and is discussed on p. 841. Glucocorticoid deficiency resulting from pituitary dysfunction is also called secondary hypoadrenocorticism. Destructive lesions in the pituitary gland or hypothalamus, the long-term administration of exogenous glucocorticoids, and idiopathic loss of function are the most common causes of secondary adrenal insufficiency. Naturally occurring, isolated hypoaldosteronism is rare in dogs and cats.

#### **Clinical Features**

# **SIGNALMENT**

Hypoadrenocorticism is typically a disease of young to middle-aged female dogs, with a median age of 4 to 6 years and a range of 2 months to 12 years. Dogs with glucocorti-

coid-deficient hypoadrenocorticism tend to be older at the time of diagnosis than dogs with mineralocorticoid and glucocorticoid deficient hypoadrenocorticism. Breeds reported to be at increased risk for hypoadrenocorticism are listed in Box 53-6. Hypoadrenocorticism is rare in cats. There is no apparent sex-related predisposition in cats, although it tends to occur in young to middle-aged cats (average age 6 years). Hypoadrenocorticism can, however, occur in aged dogs and cats as well.

# CLINICAL SIGNS AND PHYSICAL **EXAMINATION FINDINGS**

Clinical signs and physical examination findings are listed in Box 53-7. The most common clinical manifestations are related to alterations in the gastrointestinal tract and mental status and include lethargy, anorexia, vomiting, and weight loss. Weakness is also a common client complaint. Additional physical examination findings may include dehydration, bradycardia, weak femoral pulses, and abdominal pain. Hyperkalemia and hypoadrenocorticism should be suspected in an animal with bradycardia and signs consistent with hypovo-

lemia. Bradycardia by itself, however, is not pathognomonic for hypoadrenocorticism, especially in an otherwise healthy dog. Similarly, dogs with hypoadrenocorticism can have normal heart rates. Polyuria and polydipsia are rarely presenting signs, although they may surface during the taking of a complete history.

Clinical signs are often vague and easily ascribed to more common disorders involving the gastrointestinal and urinary tracts. Observant clients may occasionally describe an illness with a waxing-waning or episodic course; however, this bit of historic information is the exception rather than the rule. Most dogs with hypoadrenocorticism are first seen because of progressive problems that vary in severity, depending on the degree of stress and the adrenocortical reserve.

If hyponatremia and hyperkalemia become severe, the resultant hypovolemia, prerenal azotemia, and cardiac arrhythmias may result in an addisonian crisis. The clinical manifestations are as previously described; the only difference is in the severity of signs. In severe cases the animal may be presented in shock and be moribund. An addisonian crisis must be differentiated from other life-threatening disorders, such as diabetic ketoacidosis, necrotizing pancreatitis, acute hepatitis, septic peritonitis, and acute renal failure.

#### **CLINICAL PATHOLOGY**

Several abnormalities may be identified on a CBC, serum biochemistry panel, and urinalysis (Box 53-8). Hyperkalemia, hyponatremia, and hypochloremia are the classic electrolyte alterations in animals with adrenal insufficiency and

Isosthenuria to hypersthenuria

are perhaps the most important evidence ultimately used to establish a diagnosis of hypoadrenocorticism. Serum sodium concentrations vary from normal to as low as 105 mEq/L (mean 128 mEq/L), and serum potassium concentrations vary from normal to greater than 10 mEq/L (mean 7.2 mEq/L). The sodium: potassium ratio reflects changes in these electrolyte concentrations in serum and has been frequently used as a diagnostic tool to identify adrenal insufficiency. The normal ratio varies between 27:1 and 40:1. Values are often less than 27 and may be less than 20 in animals with primary adrenal insufficiency.

Electrolyte alterations by themselves can be misleading. Normal serum electrolyte concentrations do not rule out adrenal insufficiency. Electrolyte abnormalities may not be evident in the early stages of the disorder, when clinical signs result from glucocorticoid deficiency, and do not develop with secondary adrenal insufficiency caused by pituitary failure. Alternatively, other disorders can cause alterations in serum electrolyte concentrations that mimic adrenal insufficiency, most notably disorders involving the hepatic, gastrointestinal, and urinary systems (see Boxes 55-2 and 55-3). For most disorders a thorough history and physical examination, together with a critical evaluation of results of the CBC, serum biochemistry panel, and urinalysis, allow the clinician to prioritize the potential differential diagnoses. Important clues for hypoadrenocorticism include lack of a stress leukogram in a sick dog or cat and identification of hypoalbuminemia, hypocholesterolemia, hypoglycemia, or a combination of these on the serum biochemistry panel.

The most challenging aspect of diagnosis is the differentiation between acute renal failure and primary adrenal insufficiency. The azotemia of adrenal insufficiency occurs secondary to reduced renal perfusion and an associated decrease in glomerular filtration rate after the onset of hypovolemia and hypotension. A compensatory increase in urine specific gravity to greater than 1.030 allows prerenal azotemia to be differentiated from primary renal azotemia and therefore adrenal insufficiency to be differentiated from acute renal failure, respectively.

Unfortunately, many hypoadrenal dogs and cats have an impaired ability to concentrate urine because of chronic urinary sodium loss, depletion of the renal medullary sodium content, loss of the normal medullary concentration gradient, and impaired water resorption by the renal collecting tubules. As a result, some hypoadrenal dogs and cats with prerenal azotemia have urine specific gravities in the isosthenuric range (i.e., 1.007 to 1.015). Fortunately, the initial therapy for acute renal failure is similar to that used for adrenal insufficiency. Ultimately, the differentiation between these two disorders must rely on testing of the pituitary-adrenocortical axis and the animal's response to initial fluid and other supportive therapy.

## **ELECTROCARDIOGRAPHY**

Hyperkalemia depresses cardiac conduction and causes characteristic alterations on an electrocardiogram (ECG; see Box 55-4). The severity of the ECG abnormalities correlates with the severity of hyperkalemia. The ECG can be used as a diagnostic tool to identify and estimate the severity of hyperkalemia and as a therapeutic tool to monitor changes in the blood potassium concentration during therapy.

#### DIAGNOSTIC IMAGING

Hypoadrenal dogs and cats with severe hypovolemia often have microcardia, a descending aortic arch that is flattened and has a decreased diameter, and a narrow caudal vena cava, as seen on lateral thoracic radiographs. These findings are a crude means of evaluating the degree of hypovolemia and hypotension. Concurrent generalized megaesophagus may be evident and may resolve in response to treatment for the hypoadrenocorticism. Abdominal ultrasonography may reveal small adrenal glands (i.e., maximum width less than 0.3 cm), a finding suggestive of adrenocortical atrophy. However, finding normal-size adrenal glands does not rule out hypoadrenocorticism.

# Diagnosis

Hypoadrenocorticism is often tentatively diagnosed on the basis of the history; physical examination findings; clinicopathologic findings; and, in the case of primary adrenal insufficiency, identification of appropriate electrolyte abnormalities. Results of an ACTH stimulation test confirm the diagnosis (see Table 53-2). Baseline serum cortisol concentrations of greater than 2 µg/dl are inconsistent with the diagnosis of hypoadrenocorticism, but baseline serum cortisol concentrations of 2 µg/dl or less do not confirm the diagnosis. UCCRs are not reliable for confirming the diagnosis. One major criterion is used in confirming the diagnosis of adrenal insufficiency: a post-ACTH serum cortisol concentration less than 2 µg/dl (Fig. 53-14). A post-ACTH serum cortisol concentration of 4 µg/dl or greater is inconsistent with the diagnosis of adrenal insufficiency. Post-ACTH serum cortisol values between 2 and 4 µg/dl are equivocal and may occur with relative adrenal insufficiency-a syndrome defined as inadequate production of cortisol in relation to increased demand during periods of critical illness such as sepsis. Prolonged or excessive inflammatory cytokine activity suppresses pituitary and adrenal function in humans and possibly in dogs as well. In a recent study by Burkitt et al. (2007), dogs with severe sepsis had a suppressed response of the adrenal cortex to exogenously administered ACTH, an increase in serum cortisol concentration of less than 3 µg/dl after ACTH administration, and resolution of the relative adrenal insufficiency after resolution of the illness.

Results of the ACTH stimulation test do not distinguish dogs and cats with naturally occurring primary adrenal insufficiency from those with secondary insufficiency resulting from pituitary failure, dogs and cats with secondary insufficiency resulting from prolonged iatrogenic glucocorticoid administration, or dogs with primary adrenocortical destruction caused by mitotane or trilostane overdosing.

Differentiation of Primary Versus Secondary Hypoadrenocorticism

	PRIMARY HYPOADRENOCORTICISM	PRIMARY ATYPICAL HYPOADRENOCORTICISM	SECONDARY HYPOADRENOCORTICISM
Serum electrolytes	Hyperkalemia Hyponatremia	Normal	Normal
ACTH stimulation test Post-ACTH cortisol Post-ACTH aldosterone Endogenous ACTH	Decreased Decreased Increased	Decreased Normal Increased	Decreased Normal Decreased

ACTH, Adrenocorticotropic hormone.

Concurrent abnormal serum electrolyte concentrations imply the existence of primary adrenal insufficiency and the need for mineralocorticoid and glucocorticoid replacement therapy. Normal serum electrolyte concentrations do not differentiate between primary hypoadrenocorticism that progresses and primary hypoadrenocorticism that does not progress to mineralocorticoid deficiency or between primary hypoadrenocorticism and secondary hypoadrenocorticism (see the section on atypical hypoadrenocorticism). If secondary hypoadrenocorticism can be documented, only glucocorticoid replacement therapy is indicated. Primary and atypical or secondary hypoadrenocorticism can be differentiated prospectively by periodically measuring serum electrolyte concentrations, by measuring baseline endogenous ACTH concentration, or by measuring plasma aldosterone concentrations during the ACTH stimulation test (Table 53-5). In theory, measurement of plasma aldosterone concentration should be helpful in distinguishing between the various forms of adrenal insufficiency. Unfortunately, there is no clear demarcation in plasma aldosterone concentrations between these groups of dogs.

#### **Treatment**

The aggressiveness of therapy depends on the clinical status of the animal and the nature of the insufficiency (i.e., glucocorticoid or mineralocorticoid or both). Many dogs and cats with primary adrenal insufficiency are presented in varying stages of an acute addisonian crisis, requiring immediate, aggressive therapy. In contrast, dogs and cats with isolated glucocorticoid deficiency often have a chronic course that poses more of a diagnostic than a therapeutic challenge.

# THERAPY FOR ACUTE ADDISONIAN CRISIS

An acute addisonian crisis involves both a mineralocorticoid and a glucocorticoid deficiency. The treatment of acute primary adrenal insufficiency is directed toward correcting hypotension, hypovolemia, electrolyte imbalances, and metabolic acidosis; improving vascular integrity; and providing

#### Initial Treatment for Acute Addisonian Crisis

#### **Fluid Therapy**

Type: 0.9% saline solution
Rate: 40 to 80 ml/kg/h IV initially
Potassium supplementation: contraindicated

Dextrose: 5% dextrose infusion (100 ml of 50% dextrose

per liter of fluids)

# **Glucocorticoid Therapy**

Dexamethasone sodium phosphate, 0.5 to 1.0 mg/kg IV, repeat q12h at dosage of 0.05 to 0.1 mg/kg in IV fluids until oral prednisone can be administered.†

Alternatively, hydrocortisone hemisuccinate or hydrocortisone phosphate,\* 2 to 4 mg/kg IV or prednisolone sodium succinate,\* 4 to 20 mg/kg IV, then dexamethasone sodium phosphate, 0.05 to 0.1 mg/kg in IV fluids q12h.

#### Mineralocorticoid Therapy

Desoxycorticosterone pivalate (DOCP; Novartis), 2.2 mg/kg IM q25 days initially.

#### **Bicarbonate Therapy**

Indicated if  $HCO_3$  <12 mEq/L or total venous  $CO_2$  <12 mmol/L or animal is severely ill. mEq  $HCO_3$  = body weight (kg) × 0.5 × base deficit (mEq/L); if base deficit unknown, use 10 mEq/L. Add one quarter of calculated  $HCO_3$  dose to IV fluids and administer over 6 hours. Repeat only if plasma  $HCO_3$  remains <12 mEq/L.

IV, Intravenous; IM, intramuscular.

\* Assays to measure cortisol may measure hydrocortisone and prednisolone, interfering with interpretation of the adrenocorticotropic hormone stimulation test result.

† Higher doses of glucocorticoids may be required if the dog or cat is in shock.

an immediate source of glucocorticoids (Box 53-9). Because death resulting from hypoadrenocorticism is often attributed to vascular collapse and shock, rapid correction of hypovolemia is the first and most important therapeutic priority. Physiologic saline solution is the IV fluid of choice because it aids in correcting hypovolemia, hyponatremia, and hypochloremia. Hyperkalemia is reduced by simple dilution and by improved renal perfusion. Potassium-containing fluids (see Table 55-2) are relatively contraindicated but should be used in lieu of not giving IV fluids at all.

If hypoglycemia is suspected or known to be present, 50% dextrose should be added to the IV fluids to produce a 5% dextrose solution (i.e., 100 ml of 50% dextrose per liter of fluids). The addition of dextrose to isotonic solutions produces a hypertonic solution that ideally should be administered through a central vein to minimize phlebitis.

Dogs and cats with acute adrenal insufficiency usually have a mild metabolic acidosis that does not require therapy. Fluid therapy alone corrects the mild acidosis as hypovolemia lessens and tissue perfusion and glomerular filtration rate improve. If the total venous carbon dioxide or the serum bicarbonate concentration is less than 12 mmol/L or 12 mEq/L, respectively, conservative bicarbonate therapy is indicated. In a severely ill animal in which laboratory results are not yet known, a base deficit of 10 mEq/L can be assumed to be present. The milliequivalents of bicarbonate needed to correct the acidosis can be determined from the following equation:

# Bicarbonate deficit (mEq/L) = Body weight (kg) $\times$ 0.5 $\times$ Base deficit (mEq/L)

One fourth of the calculated bicarbonate dose should be administered in the IV fluids during the initial 6 to 8 hours of therapy. The acid-base status of the animal should be reassessed at the end of this time. Rarely, a dog or cat may require additional parenterally administered sodium bicarbonate.

Sodium bicarbonate therapy helps correct the metabolic acidosis and also decreases the serum potassium concentration. The intracellular movement of potassium ions after bicarbonate administration, in conjunction with the dilutional effects of saline fluid therapy and improved renal perfusion, is quite effective in lowering the serum potassium concentration and returning any ECG abnormalities toward normal. Additional therapy to rapidly correct life-threatening hyperkalemia is rarely needed (see Box 55-3).

Glucocorticoid and mineralocorticoid therapy is also indicated in the initial management of an acute addisonian crisis. Ideally, glucocorticoids should not be given until after completion of the ACTH stimulation test. IV infusion of saline is usually sufficient therapy during the initial 1 or 2 hours while the ACTH stimulation test is being completed. Dexamethasone does not interfere with the cortisol assay and can be used if glucocorticoid therapy cannot be delayed. Our glucocorticoid of choice for treating an acute addisonian crisis is dexamethasone sodium phosphate, given intra-

venously at an initial dosage of 0.5 to 1.0 mg/kg and repeated q12h at a dose of 0.05 to 0.1 mg/kg in the IV solution until oral medication can be safely given. Rapid-acting, water-soluble glucocorticoids such as hydrocortisone sodium succinate, hydrocortisone hemisuccinate, hydrocortisone phosphate, and prednisolone sodium succinate may be measured by the cortisol assay, causing falsely increased cortisol results, and should not be administered until after the ACTH stimulation test is completed. We do not routinely use these glucocorticoids for treating acute adrenal insufficiency.

Currently available mineralocorticoid supplements include DOCP (Percorten-V; Novartis Pharmaceuticals) and fludrocortisone acetate (Florincf; ER Squibb & Sons). Both are intended for the long-term maintenance therapy of primary adrenal insufficiency. Injectable DOCP is the preferred mineralocorticoid for the treatment of a sick dog or cat suspected of having adrenal insufficiency. The drug is initially administered at a dose of 2.2 mg/kg intramuscularly or subcutaneously every 25 days initially. In an animal in an emergency hypoadrenal crisis, the drug should be administered intramuscularly. The IV administration of saline solution and the intramuscular administration of DOCP correct electrolyte abnormalities in most hypoadrenal animals within 24 hours. There are no adverse reactions to a single injection of DOCP administered to dogs subsequently shown to have normal adrenocortical function. Atrial natriuretic peptide provides natural protection against hypernatremia. Fludrocortisone acetate is also an effective treatment. However, it is available only in tablet form, and most dogs and cats are too ill to receive oral therapy initially.

Most dogs and cats with acute adrenal insufficiency show dramatic clinical and biochemical improvement within 24 to 48 hours. Over the ensuing 2 to 4 days the animal should be gradually switched from IV fluids to oral water and food. Maintenance mineralocorticoid and glucocorticoid therapy should be initiated. If the animal fails to make this transition smoothly, persistent electrolyte imbalance, insufficient glucocorticoid supplementation, a concurrent endocrinopathy (e.g., hypothyroidism), or concurrent illness (most notably renal damage or pancreatitis resulting from poor perfusion and hypoxia caused by adrenal insufficiency) should be suspected.

# MAINTENANCE THERAPY FOR PRIMARY ADRENAL INSUFFICIENCY

Mineralocorticoids and usually glucocorticoids are required for maintenance of the dog or cat with primary adrenal insufficiency. The preferred mineralocorticoid supplementation is injectable DOCP, which slowly releases the hormone at a rate of 1 mg/day/25 mg suspension. The initial dosage is 2.2 mg/kg body weight, given intramuscularly or subcutaneously every 25 days. Subsequent adjustments are based on results of serum electrolyte concentrations, which are initially measured 12 and 25 days after each of the first two or three DOCP injections. If the dog or cat has hyponatremia or hyperkalemia (or both), on day 12 the next dose should be increased by approximately 10%. If the day 12 electrolyte

profile is normal but the day 25 profile is abnormal, the interval between injections should be decreased by 48 hours. DOCP is very effective in normalizing serum electrolyte concentrations. The only adverse reaction is polyuria and polydipsia that improve after reduction of the DOCP dose. Most dogs (and presumably cats) receiving DOCP also require a low dose of glucocorticoids (prednisone, 0.25 mg/kg q12h initially).

Drawbacks to DOCP are problems with availability and the inconvenience and expense associated with the need to make monthly visits to the veterinarian for the injection. To minimize the inconvenience and expense, the client is routinely taught to give the injection subcutaneously at home. Every third or fourth treatment, the client should bring the dog or cat into the clinic for a complete physical examination, measurement of serum electrolyte concentrations, and administration of DOCP to ensure that problems with the administration of DOCP have not developed. Once the dog or cat is healthy and serum electrolyte concentrations are stable, the amount of DOCP administered can be decreased by 10% increments initially and the frequency of DOCP administration can be shortened to every 21 days to allow lower doses of DOCP to be administered (typically about 1.5 mg/kg/injection), thereby decreasing the expense of treatment. The goal is to identify the lowest dosage of DOCP that maintains the health of the dog or cat and keeps serum electrolyte concentrations in the reference

Fludrocortisone acetate (Florinef) is another commonly used mineralocorticoid supplement. The initial dose is 0.02 mg/kg/day, divided into two doses, and administered orally. Subsequent adjustments in the dose are based on serum electrolyte concentrations, which are initially assessed every 1 to 2 weeks. The goal is to reestablish normal serum sodium and potassium concentrations. The dose of fludrocortisone acetate must typically be increased during the first 6 to 18 months of therapy. This increasing need may reflect the continuing destruction of the adrenal cortices. After this time the dose usually plateaus and remains relatively stable.

The major drawbacks to oral therapy with fludrocortisone acetate are the wide range in the doses required to control serum electrolyte concentrations; the development of polyuria, polydipsia, and incontinence in some dogs (presumably caused by the potent glucocorticoid activity of this drug); resistance to the effects of the drug, which has been observed in some animals; and persistent mild hyperkalemia and hyponatremia in some animals. Ineffectiveness of fludrocortisone acetate should be suspected when clients report that their pet is "just not right" and hyponatremia and hyperkalemia persist despite high dosages of the mineralocorticoid supplement. The concurrent administration of hydrocortisone hemisuccinate or oral salt may help alleviate the electrolyte derangements in dogs and cats in which fludrocortisone acetate by itself is not completely effective. Alternatively, switching to DOCP should be considered.

Glucocorticoid supplementation is initially indicated for all dogs and cats with primary adrenal insufficiency. Prednisone (dogs) and prednisolone (cats) is given at an initial dose of 0.25 mg/kg twice a day orally. Over the ensuing 1 to 2 months the dose of prednisone or prednisolone should gradually be reduced to the lowest amount given once a day that still prevents signs of hypocortisolism. Approximately 50% and fewer than 10% of dogs receiving fludrocortisone and DOCP, respectively, ultimately do not require glucocorticoid medication, except during times of stress. All clients should have glucocorticoids available to administer to their dogs and cats in times of stress. Veterinarians should also be aware of the increased glucocorticoid requirements of hypoadrenal dogs and cats undergoing surgery or during times of illness with a nonadrenal-related disease. The glucocorticoid dose being administered should be doubled on days when increased stress is anticipated.

The most common reason for persistence of clinical signs despite appropriate treatment is inadequate glucocorticoid supplementation. When healthy and in a nonstressed environment, dogs and cats with adrenal insufficiency typically require small amounts of prednisone or prednisolone, if any. However, when stressed or ill, these same animals may require large amounts of prednisone or prednisolone (i.e., 0.25 to 0.5 mg/kg) given twice a day. Failure to provide adequate amounts of glucocorticoids can lead to persistent and worsening lethargy, inappetence, and vomiting. The amount of prednisone or prednisolone required to offset the deleterious effects of stress and illness is variable and unpredictable. As such, it is always better to err on the high end of the dosage range and then gradually decrease the dosage over the ensuing weeks.

#### **Prognosis**

The prognosis in dogs and cats with adrenal insufficiency is usually excellent. The most important factors in determining an animal's long-term response to therapy are client education about the disease and client dedication to treatment. If there is good client-veterinarian communication, if frequent rechecks are performed, and if clients are conscientious about carrying out therapy, dogs and cats with adrenal insufficiency can have a normal life expectancy.

#### ATYPICAL HYPOADRENOCORTICISM

Some dogs and cats with hypoadrenocorticism present to the veterinarian with clinical signs of glucocorticoid deficiency but with serum electrolyte concentrations that are within the reference range at initial presentation. A deficiency in glucocorticoid but not mineralocorticoid secretion is referred to as *atypical hypoadrenocorticism*. Glucocorticoid deficiency may be adrenocortical in origin (primary atypical hypoadrenocorticism; most common) or may result from impaired secretion of ACTH by the pituitary gland (secondary hypoadrenocorticism). Baseline endogenous plasma ACTH concentrations are normal or increased when the primary problem is adrenal in origin and decreased when the primary problem is pituitary in origin (Table 53-5). Glucocorticoid

but not mineralocorticoid deficiency of adrenal origin may represent a dog or cat in the early stages of development of typical primary hypoadrenocorticism with destruction of the zona fasciculata more advanced than destruction of the zona glomerulosa. Mineralocorticoid deficiency and abnormal serum electrolyte concentrations develop weeks to months later. In some dogs and cats glucocorticoid deficiency does not progress to mineralocorticoid deficiency. The etiology for this form of hypoadrenocorticism is not known, although drugs such as megesterol acetate, mitotane, and trilostane are recognized causes.

Glucocorticoid deficiency resulting from pituitary dysfunction is called *secondary hypoadrenocorticism*. Destructive lesions (e.g., neoplasia, inflammation) in the pituitary gland or hypothalamus and the long-term administration of exogenous glucocorticoids are the most common recognized causes of secondary adrenal insufficiency. Adrenocortical atrophy may develop after the injectable, oral, or topical administration of glucocorticoids. Adrenal function usually returns within 2 to 4 weeks after the medication is discontinued, unless long-acting depot forms of glucocorticoids are used.

Glucocorticoid-deficient hypoadrenocorticism is usually identified during the diagnostic evaluation of dogs and cats with chronic, vague gastrointestinal clinical signs such as lethargy, anorexia, vomiting, diarrhea, and weight loss. Results of routine blood and urine tests are typically normal. Diagnosis requires an ACTH stimulation test (see p. 822). Therapy involves the administration of glucocorticoids, as previously described for the treatment of primary hypoadrenocorticism. The exception is secondary adrenal insufficiency induced by the overzealous administration of glucocorticoids, in which case therapy revolves around a gradual reduction in the dose and frequency of administration, with eventual discontinuation of the medication. Dogs and cats with secondary adrenal insufficiency should not have mineralocorticoid deficiency. The periodic measurement of serum electrolytes is advisable because primary glucocorticoid-deficient adrenal insufficiency and dogs and cats believed to have secondary adrenal insufficiency may progress to mineralocorticoid deficiency months after glucocorticoid-deficient hypoadrenocorticism is diagnosed.

#### **PHEOCHROMOCYTOMA**

#### **Etiology**

Pheochromocytoma is a catecholamine-producing tumor derived from the chromaffin cells of the adrenal medulla. Pheochromocytomas are uncommon in dogs and rare in cats. Pheochromocytomas are usually solitary, slow-growing tumors ranging in size from nodules of less than 0.5 cm in diameter to masses greater than 10 cm in diameter. Pheochromocytoma involving both adrenal glands has been reported. Pheochromocytoma should be considered a malignant tumor in dogs and cats. Pheochromocytomas commonly invade into the lumen of the adjacent phren-

icoabdominal vein and caudal vena cava, entrap and compress the caudal vena cava and phrenicoabdominal vein, or both (see Fig. 53-8). Mural invasion or luminal narrowing of the aorta, renal vessels, adrenal vessels, and hepatic veins and infiltration into the adjacent kidney and body wall may also occur. Distant sites of metastasis include the liver, lung, regional lymph nodes, bone, and CNS. Paragangliomas are tumors arising from chromaffin cells located outside of the adrenal medulla, most commonly near the sympathetic ganglia, and are rare in dogs and cats.

#### **Clinical Features**

Pheochromocytomas occur most commonly in older dogs and cats, with a median age of 11 years at the time of diagnosis in dogs. There is no apparent sex- or breed-related predisposition.

Clinical signs and physical examination findings develop as a result of the space-occupying nature of the tumor and its metastatic lesions or as a result of excessive secretion of catecholamines (Table 53-6). The most common clinical signs are generalized weakness and episodic collapse. The most common abnormalities identified during physical examination involve the respiratory, cardiovascular, and musculoskeletal systems and include excessive panting, tachypnea, tachycardia, weakness, and muscle wasting. Excess catecholamine secretion may also cause severe systemic hypertension, resulting in nasal and retinal hemorrhage and

<sup>\*</sup>Common signs and physical examination findings.

retinal detachment. Because catecholamine secretion is sporadic and unpredictable, clinical manifestations and systemic hypertension tend to be paroxysmal and are usually not evident at the time the dog is examined. Because clinical signs and physical examination findings are often vague, nonspecific, and easily associated with other disorders, pheochromocytoma is often not considered a possible differential diagnosis until an adrenal mass is identified with abdominal ultrasound.

#### **Diagnosis**

Pheochromocytoma should be on the list of differential diagnoses for dogs presenting with clinical signs suggestive of catecholamine excess, dogs with an unexpected adrenal mass identified by abdominal ultrasound, and dogs that develop unexpected problems with systemic hypertension or cardiac arrythmias during anesthesia. Pheochromocytoma may also be an unexpected or incidental finding at necropsy or may cause sudden collapse and death from a sudden, massive, and sustained release of catecholamines by the tumor.

There are no consistent abnormalities identified in the CBC, serum biochemistry panel, or urinalysis that would raise suspicion for pheochromocytoma. A history of acute or episodic collapse, the identification of appropriate respiratory and cardiac abnormalities during physical examination, the documentation of systemic hypertension, and identification of an adrenal mass by abdominal ultrasonog-

raphy are most helpful in establishing a tentative diagnosis of pheochromocytoma. Systemic hypertension may be sustained or episodic. Failure to document systemic hypertension in a dog with appropriate clinical signs does not rule out a diagnosis of pheochromocytoma.

The ultrasound identification of an adrenal mass with a normal-size contralateral adrenal gland is perhaps the most important clue for pheochromocytoma. Pheochromocytoma is one of several differentials for an adrenal mass (Table 53-7; see also the discussion of incidental adrenal mass). The primary differential diagnosis is adrenal-dependent hyperadrenocorticism. Interestingly, many of the clinical signs (e.g., panting, weakness) and blood pressure alterations seen in dogs with hyperadrenocorticism (common) are similar to those seen in dogs with pheochromocytoma (uncommon). In addition, pheochromocytoma and adrenocortical carcinoma both invade adjacent structures and cause tumor thrombi in the phrenicoabdominal vein and caudal vena cava. Kyles et al. (2003) found 6 of 11 dogs with pheochromocytoma and 6 of 28 dogs with an adrenocortical tumor had tumor thrombi. It is important to rule out adrenaldependent hyperadrenocorticism before focusing on pheochromocytoma in a dog with an adrenal mass.

Measurement of urinary catecholamine concentrations or their metabolites can strengthen the tentative diagnosis of a pheochromocytoma. Unfortunately, these tests are not commonly performed in dogs and cats. As a result, the antemortem definitive diagnosis of a pheochromocytoma ulti-

mately relies on histologic evaluation of the surgically excised adrenal mass.

#### **Treatment**

A period of medical therapy to reverse the effects of excessive adrenergic stimulation, followed by surgical removal of the tumor, is the treatment of choice for pheochromocytoma. The success of chemotherapy and radiation therapy in humans with pheochromocytoma has been limited, and results of chemotherapy or radiation therapy for the treatment of pheochromocytoma in dogs or cats has not been reported. Mitotane is ineffective for treating tumors arising from the adrenal medulla. Long-term medical therapy is primarily designed to control excessive catecholamine secretion.

Potentially life-threatening complications are common during the perioperative period, especially during induction of anesthesia and manipulation of the tumor during surgery. The most worrisome complications include episodes of acute, severe hypertension (systolic arterial blood pressure of more than 300 mm Hg), episodes of severe tachycardia (heart rate of more than 250 beats/min) and arrhythmias, and hemorrhage. Preoperative α-adrenergic blockade is indicated to prevent severe clinical manifestations of hypertension in the preoperative period, to reverse the hypovolemia that is frequently present, and to promote a smooth anesthetic induction. Phenoxybenzamine is the drug of choice for α-adrenergic blockade. Our current protocol for the management of hypertension in dogs with pheochromocytoma includes preoperative phenoxybenzamine and intraoperative phentolamine. Our initial dosage of phenoxybenzamine is 0.5 mg/kg q12h. Unfortunately, many dogs with pheochromocytoma have episodic clinical signs and hypertension, making it difficult to adjust dosage on the basis of improvement in clinical signs and blood pressure. In addition, this dosage is often ineffective in preventing severe hypertension during surgery. Therefore we gradually increase the phenoxybenzamine dosage every few days until clinical signs of hypotension (e.g., lethargy, weakness, syncope), adverse drug reactions (e.g., vomiting), or a maximum dosage of 2.5 mg/kg q12h is attained. Surgery is recommended 1 to 2 weeks later. The drug should be continued until the time of surgery. If severe persistent tachycardia is identified, β-adrenergic antagonist therapy (e.g., propranolol: 0.2 to 1.0 mg/kg, per os, q8h; atenolol: 0.2 to 1.0 mg/kg, PO, q24h to q12h) should be used during the preoperative period but only after α-adrenergic blockade has been initiated. Complications may still occur despite prior treatment with α-adrenergic blocking drugs; close monitoring of the dog during the perioperative period is critical for a successful outcome after adrenalectomy. (See Suggested Readings for more information on the perioperative and surgical management of dogs with a pheochromocytoma.)

Long-term medical management is designed to control excessive catecholamine secretion. The α-adrenergic blocking drug phenoxybenzamine (0.50 mg/kg, administered

orally q12h initially) is used to prevent severe clinical manifestations of hypertension. Propranolol or atenolol may also be necessary to control tachycardia and cardiac arrhythmias. However, propranolol and atenolol should be given only after  $\alpha$ -adrenergic blockade has been initiated because severe hypertension may develop after blockade of  $\beta$ -receptormediated vasodilation in skeletal muscle.

#### **Prognosis**

The prognosis depends in part on the size of the adrenal mass, presence of metastasis or local invasion of the tumor into adjacent blood vessels or organs (e.g., kidney), avoidance of perioperative complications if adrenalectomy is performed (i.e., hypertension, cardiac arrhythmias, respiratory distress, and hemorrhage), and the presence and nature of concurrent disease. Surgically excisable tumors carry a guarded to good prognosis. Survival time in our dogs that underwent adrenalectomy and survived the immediate postoperative period ranged from 2 months to longer than 3 years. If metastatic disease is not present, perioperative complications are prevented, and serious concurrent disease not present, the dog has the potential to live a significant length of time (i.e., more than a year). Pretreatment with an αadrenergic blocking drug before surgery and the involvement of an experienced anesthesiologist and surgeon with expertise in adrenal surgery help minimize potentially serious perioperative complications associated with anesthesia and digital manipulation of the tumor. Medically treated dogs can live longer than 1 year from the time of diagnosis if the tumor is relatively small (less than 3 cm diameter), vascular invasion is not present, and treatment with an α-adrenergic blocking drug is effective in minimizing the deleterious effects of episodic excessive catecholamine secretion by the tumor. Most dogs die or are euthanized because of complications caused by excessive catecholamine secretion, complications caused by tumor-induced venous thrombosis, or complications caused by invasion of the tumor or its metastases into surrounding organs.

#### INCIDENTAL ADRENAL MASS

Ultrasonography has become a routine diagnostic tool for the evaluation of soft tissue structures in the abdominal cavity. One consequence of abdominal ultrasonography is the unexpected finding of a seemingly incidental adrenal mass. Many factors determine the aggressiveness of the diagnostic and therapeutic approach to an adrenal mass, including the severity of concurrent problems, the original reason for performing abdominal ultrasound, the age of the dog or cat, the likelihood that the mass is hormonally active, the likelihood that the mass is a malignant or benign tumor, the size and invasiveness of the mass, and the client's desires and willingness to pursue the problem. The first consideration is to be certain that an adrenal mass exists. Abdominal ultrasound should always be repeated to confirm that the mass is

a repeatable finding. An adrenal mass is suspected when the maximum width of the adrenal gland exceeds 1.5 cm, there is loss of the typical kidney-bean shape of the gland, and there is asymmetry in shape and size between the affected adrenal gland and the contralateral adrenal gland. Bulbous enlargement of the cranial or caudal pole of the adrenal gland is common in dogs with normal adrenal glands and can be misinterpreted as an adrenal mass.

An adrenal mass is not always neoplastic or producing and secreting a hormone. The mass may be normal tissue, granuloma, cyst, hemorrhage, or an inflammatory nodule. Adrenalectomy is the treatment of choice if the mass is malignant and has not spread, but adrenalectomy may not be indicated if the mass is benign, small, hormonally inactive, and not invading surrounding structures. Unfortunately, it is not easy to determine whether an adrenal mass is neoplastic and malignant or benign before surgical removal and histopathologic evaluation. Guidelines to suggest malignancy include size of the mass, invasion of the mass into surrounding organs and blood vessels, and identification of additional mass lesions with abdominal ultrasound and thoracic radiographs. The bigger the mass, the more likely it is to be malignant and the more likely metastasis has occurred, regardless of findings on abdominal ultrasound and thoracic radiographs. Cytologic evaluation of specimens obtained by ultrasound-guided fine-needle aspiration of the adrenal mass may provide guidance regarding malignancy and origin of the mass (i.e., adrenal cortex versus medulla).

An adrenal tumor may secrete a hormone or be nonfunctional. Excess secretion of cortisol, catecholamines, aldosterone, progesterone, and steroid hormone precursors have been documented in dogs and cats (see Table 53-7). The most common functional adrenal tumors secrete cortisol or catecholamines. Aldosterone-secreting adrenal tumors causing primary hyperaldosteronism (Conn's syndrome) are uncommon in dogs and cats. Excessive secretion of aldosterone causes sodium retention and potassium depletion, which is manifested as increased serum sodium (greater than 155 mEq/L) and decreased serum potassium (less than 3.0 mEq/L) concentrations. Hypokalemia causes lethargy and weakness, which are the most common clinical signs of primary hyperaldosteronism. Hypernatremia causes systemic hypertension. An adrenal mass should be identified on abdominal ultrasound, and the contralateral adrenal gland should be normal in size and shape. Documenting an increased baseline plasma aldosterone concentration is used to confirm the diagnosis.

Adrenal tumors secreting progesterone, 17-hydroxyprogesterone (see the section on atypical Cushing's syndrome, p. 830), and other adrenocortical steroid precursors have also been documented in dogs and cats. Progesterone-secreting adrenal tumors are identified most commonly in cats. Excessive progesterone secretion in affected cats caused diabetes mellitus and feline fragile skin syndrome, characterized by progressively worsening dermal and epidermal atrophy, patchy endocrine alopecia, and easily torn skin (see Fig. 53-20). Clinical features mimicked feline hyperadrenocorticism, which is the primary differential diagnosis. Results of tests of the pituitary-adrenocortical axis are normal to suppressed in cats with progesterone-secreting adrenal tumors, and the contralateral adrenal gland is normal in size and shape on abdominal ultrasound. Diagnosis requires documenting an increased plasma progesterone concentration.

After discovering an incidental mass, the clinician should review the history, physical examination, and results of routine blood and urine tests for evidence of hyperadrenocorticism, hyperaldosteronism, or pheochromocytoma and should perform the appropriate tests to confirm the diagnosis. Whenever surgical removal of an adrenal mass is planned, a UCCR and an LDDS test should be evaluated and the perioperative management adjusted accordingly if test results are consistent with hyperadrenocorticism. If hormonal tests for hyperadrenocorticism are normal and clinical signs suggestive of pheochromocytoma are present, the clinician should assume that the adrenal mass is a pheochromocytoma and treat with an α-adrenergic antagonist before adrenalectomy (see p. 843). If the diagnostic evaluation does not support hyperadrenocorticism or pheochromocytoma, the anesthesiologist should be prepared to manage intraoperative blood pressure and cardiac rhythm disturbances should the mass turn out to be a pheochromocytoma.

An aggressive diagnostic and therapeutic approach is often not warranted for a small adrenal mass (less than 2 cm in maximum width), especially if the dog or cat is healthy and there are no clinical signs related to adrenal dysfunction. In these cases, it may be preferable to determine the rate of growth of the mass by repeating abdominal ultrasound initially at 2, 4, and 6 months. If the adrenal mass has not changed in size during this time, the clinician can increase the time interval between ultrasound evaluations to every 4 to 6 months (Fig. 53-21). However, if the adrenal mass is increasing in size and/or clinical signs develop, the clinician should consider adrenalectomy.

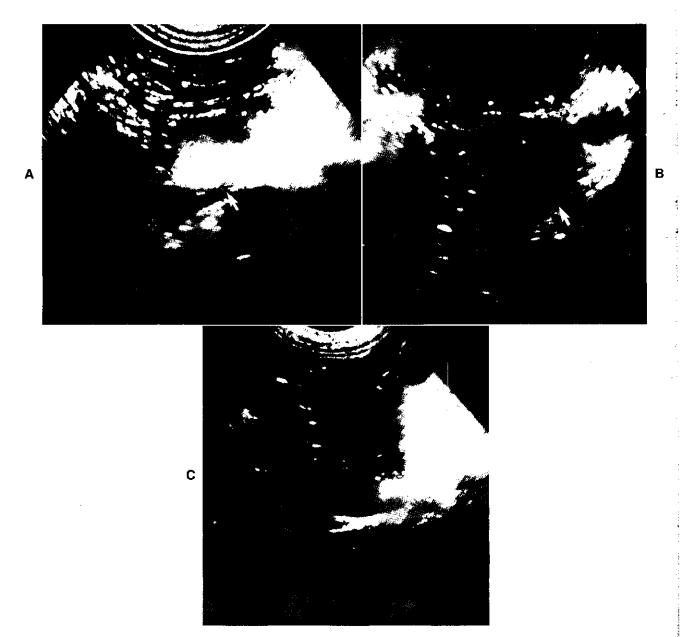

FIG 53-21

**A,** An 11-year-old male castrated Doberman Pinscher mix presented for clinical signs consistent with acute gastroenteritis. Abdominal ultrasound identified a 1.4-cm diameter adrenal mass (arrow) and a normal-size contralateral adrenal gland. The history, physical examination, and results of routine blood and urine tests were not supportive of adrenal disease, and the dog responded to symptomatic therapy for acute gastroenteritis. The adrenal mass was periodically evaluated with ultrasound. Over the ensuing 2 years the dog remained healthy and there was minimal growth or change in the echogenicity of the adrenal mass. **B,** The adrenal mass 1 year after presentation; maximum diameter was 1.8 cm. **C,** The adrenal mass 2 years after presentation; maximum diameter was 2.0 cm.

GENERIC NAME (TRADE		RECOMMENDED DOSE				
NAME)	PURPOSE	DOG	CAT			
Aminoglutethimide (Cytadren)	Treat feline hyperadrenocorticism	Not applicable	30 mg/cat PO q12h			
Calcium-injectable and oral preps	Treat hypocalcemia, hypoparathyroidism	See Box 55-7	See Box 55-7			
Carbimazole (Neo- Mercazole)	Treat feline hyperthyroidism	Not applicable	5 mg PO q12h initially; increase q 2 weeks to effect			
Chlorpropamide (Diabinase)	Treat partial central diabetes insipidus	5-20 mg/kg PO q12h	Unknown			
Chlorothiazide (Diuril)	Treat central/renal diabetes insipidus	20-40 mg/kg PO q12h	20-40 mg/kg PO q12h			
Desmopressin (DDAVP)	Treat central diabetes insipidus	1-4 drops of nasal spray in eye q12-24h; 0.1 mg tablet PO q8-12h	1-4 drops of nasal spray in eye q12-24h; 0.05 mg tablet PO q8-12h			
Desoxycorticosterone pivalate (DOCP)	Treat hypoadrenocorticism	2.2 mg/kg IM or SC q25 days	2.2 mg/kg IM or SC q 25 days			
Dexamethasone sodium phosphate	Treat acute Addisonian crisis	0.5-1.0 mg/kg IV, repeat q12h at 0.05 to 0.1 mg/kg in IV fluids	0.5-1.0 mg/kg IV, repeat q12h at 0.05-0.1 mg/kg in IV fluids			
Diazoxide (Proglycem)	Supportive treatment for β cell tumor	5 mg/kg PO q12h initially; increase as needed	Unknown			
Diethylstilbesterol	Treat estrogen-responsive dermatosis of spayed female dogs	0.1-1.0 mg PO q24h 3 weeks per month; once respond, 0.1- 1 mg q4-7 days	Not applicable			
Doxorubicin (Adriamycin)	Treat canine thyroid neoplasia	30 mg/m² BSA IV q3-6 weeks	Not applicable			
Fludrocortisone acetate (Florinef)	Treat hypoadrenocorticism	0.01 mg/kg PO q12h initially	0.05-0.1 mg/cat PO q12h			
Glipizide (Glucotrol) Glucagon USP	Treat feline type 2 diabetes Treat hypoglycemia caused by β cell neoplasia	Not applicable 5-10 ng/kg/min as continuous IV infusion; adjust dose to effect	2.5-5 mg/cat PO q12h Unknown			
Glyburide (Diabeta, Micronase)	Treat feline type 2 diabetes	Not applicable	0.625-1.25 mg/cat PO q24h			
Growth Hormone-porcine origin	Treat GH-responsive dermatosis Treat pituitary dwarfism	0.1-0.3 IU/kg SC 3 times/week for 4 to 6 wks	Unknown			
Hydrocortisone hemisuccinate	Treat acute addisonian crisis	2-4 mg/kg IV, then administer dexamethasone in IV fluids	2-4 mg/kg IV, then administer dexamethasone in IV fluids			
Hydrocortisone phosphate	Treat acute crisis	2-4 mg/kg IV, then administer dexamethasone in IV fluids	2-4 mg/kg IV, then administer dexamethasone in IV fluids			
Insulin	Treat diabetic ketoacidosis Treat diabetes mellitus Supportive treatment for hyperkalemia	See Box 52-9 See Table 52-2 See Table 55-3	See Box 52-9 See Table 52-2 See Table 55-3			
Ketoconazole (Nizoral)	Treat hyperadrenocorticism	5 mg/kg PO q12h initially; increase to effect q 2 weeks	Not recommended			
Medroxyprogesterone acetate	Treat pituitary dwarfism	2.5-5.0 mg/kg SC q 3 weeks initially	Not applicable			
Megestrol acetate (Ovaban)	Treat feline endocrine alopecia	Not applicable	2.5-5 mg/cat PO q48h; once respond, then q7-14 days			

GENERIC NAME (TRADE	elevente militaria en el Cantillo de la Cantillo de la Cantillo de la Cantillo de Cantillo	RECOMMEN	DED DOSE
NAME)	PURPOSE	DOG	CAT
Melatonin	Treat congenital adrenal hyperplasia-like syndrome, Alopecia-X	3-6 mg PO q12-24h	Not applicable
Methimazole (Tapazole)	Treat hyperthyroidism	<ol> <li>2.5 mg/dog PO q12h initially; increase q2 weeks to effect</li> </ol>	2.5 mg/cat PO q12h initially; increase q2 weeks to effect
Methyltestosterone	Treat testosterone- responsive dermatosis	1 mg/kg (max, 30 mg) PO q48h; once dog responds, then q4-7 days	Not applicable
o,p'DDD (Mitotane, Lysodren)	Treat canine hyperadrenocorticism	Induction: 25 mg/kg PO q12h until controlled Maintenance: 25-50 mg/kg PO per week initially	Not recommended
Phenoxybenzamine (Dibenzyline)	Supportive treatment for pheochromocytoma	0.5 mg/kg PO q12h initially	Unknown
Prednisolone sodium succinate	Treat acute addisonian crisis	4-20 mg/kg IV, then administer dexamethasone in IV fluids	4-20 mg/kg IV, then administer dexamethasone in IV fluids
Prednisone (dogs), prednisolone (cats)	Chronic treatment of hypoadrenocorticism	0.25 mg/kg PO q12h initially	2.5-5.0 mg/cat PO q12-24h initially
,	Supportive treatment for β cell tumor	0.25 mg/kg PO q12h initially; increase as needed	2.5 mg/cat PO q12h initially; increase as needed
Prednisolone sodium succinate (Solu-Delta- Cortef)	Treat acute addisonian crisis	4-20 mg/kg IV, then administer dexamethasone in IV fluids	4-20 mg/kg IV, then administer dexamethasone in IV fluids
Sodium levothyroxine- synthetic T4	Treat hypothyroidism	0.02 mg/kg PO q12h initially, unless formulated for q24h	0.05-0.1 mg/cat PO q12- 24h initially
Somatostatin (Octreotide)	Supportive treatment for $\beta$ cell tumor	10-40 μg/dog SC q8-12h	Unknown
Streptozotocin	Treat canine β cell tumor	500 mg/m <sup>2</sup> BSA IV during 0.9% saline diuresis q 3 weeks; see Box 52-12	Not applicable
Trilostane (Vetoryl)	Treat hyperadrenocorticism	1-2 mg/kg q 12h initially; adjust to effect	1-2 mg/kg q24h initially; adjust to effect
Vitamin D preparations	Treat hypoparathyroidism	See Box 55-7	See Box 55-7

# CHAPTER

## Disorders of Metabolism

#### CHAPTER OUTLINE

POLYPHAGIA WITH WEIGHT LOSS OBESITY HYPERLIPIDEMIA

#### POLYPHAGIA WITH WEIGHT LOSS

In most dogs and cats polyphagia is usually accompanied by weight gain, and weight loss is accompanied by partial or complete anorexia. In some, however, polyphagia with concurrent weight loss is the presenting complaint. The most common cause of polyphagia with concurrent weight loss is inadequate caloric intake (Table 54-1). Daily caloric needs may not be met if inadequate quantities of food are being fed or if the diet is not complete and balanced or is of poor quality. Alternatively, the client may not recognize changes in nutritional needs (e.g., during pregnancy and lactation and at times of strenuous exercise, such as during hunting season) and may continue to feed the animal at previously adequate caloric levels.

Endocrinopathies and gastrointestinal tract disorders also cause polyphagia and weight loss in some dogs and cats (see Table 54-1) as a result of an increase in basal metabolism (hyperthyroidism), inadequate assimilation of dietary nutrients (gastrointestinal tract disorders), or inappropriate use of nutrients (diabetes mellitus). Gastrointestinal tract disorders include parasitism, pancreatic exocrine insufficiency, infiltrative bowel disorders, lymphangiectasia, and neoplasia (most notably lymphoma). In most of these disorders the history and physical findings usually provide valuable clues to the diagnosis. For example, polyuria and polydipsia are common signs in diabetes mellitus. A thyroid nodule is usually palpable in dogs and cats with hyperthyroidism.

Bulky, voluminous stools are noted in animals with pancreatic exocrine insufficiency. Diarrhea and vomiting may occur in animals with gastrointestinal tract disorders, and palpation of the abdomen may reveal abnormal loops of intestine and mesenteric lymphadenopathy. The last condition may be discernible in animals with any of the infiltrative diseases but is especially noticeable in those with gastrointestinal tract lymphoma, eosinophilic enteritis, or histoplasmosis.

In addition to routine questions posed to the client, the clinician should assess the type of foods offered, daily caloric intake, feeding routines, and competition for food from other dogs or cats. Daily caloric requirements in cats and dogs are quite variable and depend on numerous factors, such as signalment and the amount of daily physical activity. The average daily caloric intake can be calculated using the equation for the resting energy requirement (RER): 70× body weight in kilograms raised to the power. This can be calculated on a simple calculator with a square root button. The body weight in kilograms is multiplied by itself three times, and the square root of the result is taken twice before multiplying by 70. This value for RER has a unit of kcal per day and is multiplied by a factor to derive the maintenance energy requirement (MER). The factor for a neutered cat is 1.2, an intact cat's factor is 1.4, a neutered dog's factor is 1.6, and an intact dog's is 1.8. The daily caloric requirements in any individual dog or cat may vary by as much as 50% more or less than this calculation. Although this represents a large range for normal caloric intakes, the clinician may have a greater suspicion that an inadequate amount of calories is being fed if the amount based on the diet history is closer to 50% of MER. At the same time, consumption of calories closer to 150% of MER may increase the suspicion that adequate calories are being fed but that an endocrinopathy and/or gastrointestinal tract disorder may be leading to polyphagia with concurrent weight loss. If the results of comparing the caloric intake to the calculated MER prove equivocal

Differential Diagnosis for Polyphagia and Weight Loss

#### **ETIOLOGY**

Inadequate nutrition Hyperthyroidism Diabetes mellitus Gastrointestinal disease **Parasitism** Infiltrative bowel disease: plasmacytic, lymphocytic, eosinophilic, lymphoma Histoplasmosis Lymphangiectasia Pancreatic exocrine insufficiency

Protein-losing nephropathy

Hypothalamic mass

#### **DEFINITIVE DIAGNOSTIC TESTS**

Response to diet change Serum T<sub>4</sub> and free T<sub>4</sub> concentrations Blood glucose concentration and urinalysis

Fecal examination, trial therapy Intestinal biopsy

Intestinal biopsy, serology Intestinal biopsy

Serum trypsin-like immunoreactivity, response to therapy Urinalysis, urine protein/creatinine ratio

Computed tomography, magnetic resonance imaging

or cannot be attained, simply feeding more food or calories and reassessing the patient's weight may be illuminative.

A complete blood count, serum biochemistry panel, measurement of baseline thyroxine concentration, urinalysis, and fecal examination for parasites should be done if the history and physical findings are unremarkable. Results of these tests usually help identify additional specific diagnostic tests that may be required to establish a definitive diagnosis (see Table 54-1). Inadequate nutrition should be suspected if the initial blood test results are unremarkable. Changes in the type of foods provided, daily caloric intake, and feeding routine should be made to ensure that the animal has an adequate caloric intake of a palatable and nutritionally complete and balanced food. The animal's body weight should be determined 2 and 4 weeks after the start of an appropriate diet. The resolution of signs and weight gain confirm the diagnosis. Failure to gain weight indicates problems with client compliance or the presence of occult disease, most likely disease involving the gastrointestinal tract.

#### OBESITY

Obesity is a clinical syndrome that involves the excess accumulation of body fat. Obesity is considered the most common form of malnutrition in small animal practice. Indeed, surveys suggest that 25% to 40% of cats and dogs presented to veterinary clinics are overweight or obese. The significance of obesity pertains to its role in the pathogenesis of a variety of diseases and its ability to exacerbate preexisting disease and decrease lifespan. Obesity has been associated with an increased incidence of arthritis, diabetes mellitus, hepatic lipidosis, feline lower urinary tract disease (FLUTD), urine incontinence in spayed bitches, constipation, dermatitis, cardiovascular problems, respiratory problems, and increased anesthetic and surgical risk (Box 54-1). In addition, Scarlett et al. (1998) found a threefold increase in risk of death in

BOX 54-1

Potential Adverse Effects of Obesity

Decreased lifespan

Problems with ambulation-aggravation of joint disease, intervertebral disk disease

Problems with respiration—impaired lung compliance, Pickwickian syndrome

Cardiovascular disease and systemic hypertension Exercise intolerance

Carbohydrate intolerance—predisposition for diabetes mellitus

Hyperlipidemia

Hepatic lipidosis

Predisposition for pancreatitis

Problems with constipation

Predisposition for feline lower urinary tract disease

Predisposition for urinary incontinence in spayed female dogs

Predisposition for reproductive problems—dystocia

Predisposition for dermatologic problems—seborrhea, pyoderma

Increased surgical and anesthetic risk

Increased susceptibility to infectious diseases (?)

obese middle-aged cats compared with the risk in lean middle-aged cats. In dogs Kealy et al. (2002) found that dogs that were kept lean throughout their life lived almost 2 years longer than control-group littermates that were overweight. The lean dogs also did not need treatment for co-morbidities such as osteoarthritis until later in life.

Obesity develops when energy intake consistently exceeds daily energy expenditure. Numerous environmental and social factors contribute to the development of obesity

#### Causes of Obesity in Cats and Dogs

#### **Primary Obesity**

Excess caloric intake
Energy dense food
Inappropriate feeding practices
Inadequate feeding guidelines
Ad libitum feeding
Reduced energy expenditure
Genetic predisposition
Obese client

#### Secondary Obesity

Hypothyroidism
Hyperadrenocorticism
Hyperinsulinism
Acromegaly
Hypopituitarism
Hypothalamic dysfunction
Drugs
Glucocorticoids
Progestagens
Phenobarbital
Primidone

(Box 54-2). These include decreased daily exercise as a result of confinement to the house and overfeeding of the pet. Clients may overfeed their pet because a good appetite is perceived as a sign of good health, they may use food as a palliative agent when they leave the pet on its own, they may replace exercise with food, and they often indulge begging behavior because they find it endearing. Clients also tend to feed the same volume of food each day despite changes in energy requirements and the energy density of foods provided. Daily energy requirements vary according to the environmental temperature, the life stage of the pet (i.e., growth, pregnancy, lactation, adult maintenance, old age), the neuter status, and the activity level of the pet. Therefore it is necessary to adjust the amount of food according to these factors. Feeding errors also arise when a client purchases a different type of food with a higher energy density but does not reduce the amount accordingly. It is worth noting that dry extruded foods can now range from 200 kcal per 8-ounce cup to over 600 kcal per cup. Overfeeding may also arise if the feeding guidelines provided by pet food manufacturers are incorrect. In some situations clients are simply not aware that they are overfeeding their pet. Ad libitum feeding may also predispose to overeating, particularly if the pet is bored and inactive. Likewise, highly palatable foods encourage overconsumption. Snacks and treats are a significant silent contributor to excess daily caloric intake as well. It takes only about 11 extra calories a day for a pet to gain I pound over the course of a year; many common treats provide between 50 and 100 extra calories apiece.

Obese clients may be more likely to have obese pets. The client's sedentary lifestyle may contribute to a lack of exercise by the pet, and the consumption of high-fat foods by the client may increase the likelihood that these energy-dense scraps are fed to the pet. In addition, it is possible that obese clients do not believe (or recognize) that obesity is a major problem for their pet.

Because of genetic differences, some animals have significantly lower energy requirements and therefore require fewer calories per day to maintain their ideal body weight. These genetic differences may be reflected by the increased propensity of certain dog breeds to gain weight. Breeds commonly recognized as at risk for obesity include the Labrador Retriever, Golden Retriever, Cocker Spaniel, Collie, Dachshund, Cairn Terrier, Shetland Sheepdog, Beagle, Cavalier King Charles Spaniel, and Basset Hound. Neutering has been associated with an increased risk of obesity. It has been suggested that hormonal alterations secondary to neutering may alter energy expenditure and the regulation of food intake. Obesity has been reported to be more common in female neutered dogs and male neutered cats.

Obesity is less likely to result from a disease process or drug. Indeed, it has been suggested that less than 5% of obesity is due to a disease or drug. Endocrine abnormalities associated with obesity include hypothyroidism, hyperadrenocorticism, hyperinsulinism, and acromegaly. Drugs such as progestagens and corticosteroids have been associated with the development of obesity.

#### Diagnosis

Obesity is defined as a "pathological condition characterized by an accumulation of fat much in excess of that required for optimal body function" (Mayer, 1973). However, what is an excess amount of body fat, and what is an acceptable amount? To answer these questions, the clinician must accurately determine the amount of body fat. Body fat can be assessed by techniques such as morphometric measurements, dilutional methods, bioelectrical impedance analysis, dual energy X-ray absorptiometry, densitometry, computed tomography, magnetic resonance imaging, determination of total body electrical conductivity, determination of total body potassium, and neutron activation analysis. Although numerous methods exist to determine body fat, measurement of body weight, calculation of a body condition score (BCS), and morphometric measurements remain the most clinically useful techniques in small animal practice.

Measurement of body weight is the simplest technique available and should be included in the examination of every animal. Body weight provides a rough measure of total body energy stores, and changes in weight reflect energy and protein balance.

Body condition scoring provides a quick and simple subjective assessment of the animal's body condition. The two most commonly used scoring systems in small animal practice are a 5-point system in which a BCS of 3 is considered ideal and a 9-point system in which a BCS of 5 is considered ideal. Larger numbers are used for patients with greater

adiposity. Each point above and below 5 on the 9-point system has been validated to correspond with an increase or decrease in adiposity or weight of 10% to 15%. Thus a patient that has a BCS of 7 out of 9 is 20% to 30% overweight as a result of the accumulation of adipose tissue. Likewise, pets can be classified as being thin, lean, of optimal weight, overweight, or obese (Box 54-3). The BCS technique depends on operator interpretation and does not provide any precise quantitative information concerning alteration in fat-free or lean body mass relative to fat mass.

Height and circumferential measurements of the abdomen, hip, thigh, and upper arm are commonly used to estimate the percentage of body fat in humans. Circumferential measurements have also been developed to estimate the percentage of body fat in cats. The Feline Body Mass Index (FBMI) is determined by measuring the rib cage circumference at the level of the ninth cranial rib and deter-

A

BOX 54-3

Body Condition Scoring (BCS) System for Cats and Dogs Using a 5-Point System

Thin (BCS 1/5) Underweight; no obvious body fat Lean (BCS 2/5) Skeletal structure visible; little body fat Optimal Rib cage easily palpable but not (BSC 3/5) showing; moderate amount of body fat Overweight Rib cage barely palpable; body (BCS 4/5) weight more than normal Obese (BCS 5/5) Rib cage not palpable; large amount of body fat; physical impairment resulting from excess body fat

mining the leg index measurement (LIM), which is the distance from the patella to the calcanealtuber (Fig. 54-1, A and B). The percentage of body fat can be calculated as 1.5 to 9 (rib cage measurement minus LIM) or determined by consulting a reference chart (Fig. 54-2). Cats with more than 30% body fat are candidates for a weight loss program. The FBMI is a very simple yet objective tool for determining the body fat content of the cat. In addition, it is particularly valuable in persuading clients that their cat is indeed overweight and in need of weight loss. Pelvic circumference in relation to the distance from hock to stifle has been shown to predict body fat in dogs. Whether morphometric measurements or BCS is used, providing a quantitative assessment of a patient's degree of adiposity can be helpful in diagnosing obesity, which is typically defined as being approximately 25% over one's ideal body weight.

#### **Treatment**

After determining that a patient is overweight or obese, the clinician should obtain a thorough dietary history to calculate the patient's daily caloric intake. The clinician should gather the following information:

- The name, manufacturer, and type (i.e., pouched versus canned versus dry) of the current food(s)
- The amount of food that is fed each day (pouches, cans, cups, or grams of food)
- The method of feeding (ad libitum versus meal fed)
- The person responsible for feeding the patient
- Additional persons who may feed the patient (especially children, elderly parents, or friendly neighbors)
- The number and type of snacks or human foods given each day
- The potential access to foods for other pets

**FIG 54-1 A,** Length of the lower leg (LIM) from the middle of the patella. **B,** Measurement of the rib cage circumference.

В

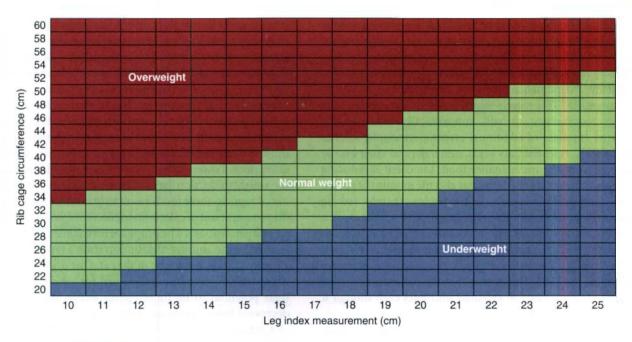

FIG 54-2 Feline body mass index (FBMI).

The patient's current body weight should be recorded and a BCS assigned. The BCS can be used to determine the percentage of body weight that must be lost. Remembering that each point above a 5 on a 9-point scale represents an additional 10% to 15% of weight over ideal, the clinician can calculate the percentage of weight that should be lost. For example, a patient that has a BCS of 8 out of 9 is 30% to 45% overweight. For reasons that will be discussed later, patients should not lose more than 2% of their body weight per week. Therefore it should be expected that most overweight and obese patients will take at least several months to lose enough adipose tissue to attain their ideal body weight. Given the necessary length of time, it is imperative to break down the ultimate goal of an ideal body weight into smaller goals that can be achieved in shorter periods of time. Therefore the clinician may recommend that the patient lose 2% to 4% of body weight every 2 weeks; later, monthly goals of 4% to 8% may be set. These shorter-term goals are typically more manageable and provide more opportunities for adjustment of a weight loss plan if needed and for praise if the plan is proving effective.

A rate of weight loss of 1% to 2% of current body weight per week is typically recommended for several reasons. First, greater rates of weight loss will require that the patient receive a very small allowance of food, which is most likely to encourage begging behavior and garbage scavenging. These undesirable behaviors, along with the small volume of food to be provided, can jeopardize client compliance. Second, weight loss greater than 2% of body weight per week is considered unhealthy and has been associated with a greater loss of lean body mass compared with fat mass. Third, rapid weight loss is most likely to result in a rebound weight gain effect after cessation of the program.

Given the large variation in energy requirement that can be seen in cats and dogs, the best method to determine the amount of calories to feed a patient to induce weight loss is the use of an accurate diet history. Typically, the weight of overweight and obese patients is relatively stable at presentation; therefore feeding 80% of the patient's current caloric intake based on an accurate diet history results in weight loss of 0.5% to 2% of body weight loss per week. In patients in which an accurate diet history cannot be determined or that are not roughly weight stable, the client may feed 80% of RER for cats and RER for dogs. Regardless of the method used to determine the number of calories to feed to initiate weight loss, clients should be told to expect to adjust the amount of food on the basis of frequent weigh-ins. Initially, it can be expected that some patients will gain weight on the new weight loss plan, some may stay weight stable, some may lose the desired amount, and some may even lose weight too quickly.

After determining the daily amount of calories to feed the patient, the clinician should consider the most suitable type of food. There are essentially two main dietary options: either feed a reduced amount of the regular maintenance food or feed a food that has been specifically formulated for weight reduction. It is not advisable to feed less of the regular food because this most likely was the food that resulted in the problem in the first place. More important, feeding a maintenance food decreases compliance and increases the risk of nutrient deficiency and unhealthy weight loss. Most foods designed for weight reduction are one-half to two-thirds less energy dense than typical maintenance foods. Therefore clients will not visually perceive as much of a decrease in "bowl fill" when feeding a food designed for weight reduction. Decreased energy density is achieved by

decreasing the fat content of the food, air-puffing kibble, increasing the moisture content of canned or pouched foods, and/or by adding fiber. There does appear to be some satiety effect by increasing "bowel fill". More significantly, canine and feline maintenance foods are formulated according to energy intake. This means that if a dog or cat eats its daily energy requirement, it will automatically consume the required amounts of additional essential nutrients, such as amino acids, essential fatty acids, minerals, and vitamins. By feeding less of the maintenance food, the client is reducing not only the amount of energy but also the amount of amino acids, fatty acids, minerals, and vitamins, thereby risking malnutrition, especially given the length of time that is often needed to achieve an ideal body condition. Conversely, foods that have been specifically formulated for weight reduction contain more essential nutrients relative to the energy content of the food. This means that the patient will receive the required amounts of essential nutrients even though it is ingesting fewer calories.

Foods formulated specifically for weight reduction typically vary according to energy density, fiber content, and caloric distribution (Tables 54-2 and 54-3). Most foods designed for weight reduction are less energy dense than maintenance foods. This enables a greater filling of both the bowl and the bowel, which should lead to increased compliance and satiety. Traditionally, higher-fiber foods are initially suggested for weight loss. Fiber is used as a bulking agent to decrease energy density and provide a satiating effect. However, there is conflicting research as to whether fiber increases satiety. Because some patients may not respond well to higher-fiber foods, some manufacturers do not use this nutritional strategy. Caloric distribution refers to the percentage of calories provided from protein, fat, and carbohydrate. Higher-protein foods have been reported to increase the proportion of fat loss while preserving or, indeed, increasing the lean body mass. The lean body mass is the most metabolically active portion of the body and includes skeletal muscle tissues. Preservation of lean body mass in humans has been shown to facilitate successful long-term maintenance of the ideal body weight once weight loss has been achieved. Lowering the percentage of calories from fat in foods helps reduce the energy density of the food because fat provides almost 2.5 times the amount of calories per gram as protein or carbohydrate does. Lower-carbohydrate foods specifically designed for weight reduction have become available. According to initial reports, these foods result in greater fat mass loss with the same amount of caloric restriction compared with highercarbohydrate foods. The proposed mechanism for this difference relates to shifting metabolism from a lypogenic state to a lypolytic state, especially in the cat. One drawback of some lower-carbohydrate foods designed for weight reduction is their potential to be more energy dense and thus have a decreased bowl- and bowel-filling effect.

Carnitine is an amino acid derivative that is vital for energy metabolism. Carnitine facilitates the movement of long-chain fatty acids across the mitochondrial membrane, where they are used for energy production. Carnitine supplementation is believed to facilitate weight loss by increasing the efficiency of "burning" fat as an energy source. However, a study evaluating the effect of carnitine supplementation on body weight loss failed to demonstrate any benefits (Center et al., 2000). Cats that received carnitine supplementation lost the same percentage of body weight in the same period of time as cats that did not receive carnitine supplementation. In addition, neither group of cats developed hepatic lipidosis.

As this chapter was being completed, a new drug (dirlotapide) has become available that helps reduce the appetites

of dogs in need of weight loss. According to the manufacturer's literature, dirlotapide is a selective microsomal triglyceride transfer protein inhibitor that blocks the assembly and release of lipoproteins into the bloodstream. The mechanism of action for producing weight loss is not completely understood, but it seems to result from reduced fat absorption and a satiety signal from lipid-filled enterocytes. Dirlotapide mainly acts locally in the gut to reduce appetite, increase fecal fat, and produce weight loss in the management of obesity in dogs. It appears that changes in long-term client feeding practices are important for prevention of weight regain after the use of this potentially promising new drug.

Once the daily caloric intake has been determined and the appropriate weight reduction food(s) chosen, the method of feeding should be determined. Ideally, the patient should receive meals rather than be fed ad libitum. The number of feedings per day can be selected to suit the client's schedule, but two to four meals per day is adequate. One member of the household should be selected to feed the patient. This will reduce inadvertent overfeeding by additional family members. If treats are typically fed or are desired, the client should be instructed to limit the number of treats to less than 10% of the daily caloric intake. Ideally, low-calorie treats should be selected. Commercial treats are available, but fruits (excluding grapes or raisins) and/or vegetables (no garlic or onions and not in patients with calcium oxalate urolithiasis) can be good alternatives for dogs and even some cats. Baby carrots are an especially good vegetable treat for dogs and contain only 4 kcal each. A small amount of lean

meat, such as skinless chicken breast, can be a good alternative treat for cats. It is also important to modify the behavior of the client such that the patient should not be allowed in the kitchen or dining room during meal preparation or eating if this is typically a tempting time to respond to begging. In addition, the client should inform and enlist the support of family members and neighbors so that they do not unknowingly give the patient additional calories. In some cases it may be useful for the client to use a food diary to record the amount of food and snacks fed each day. For other clients this technique is often met with resistance and should not be considered.

Multicat households in which one cat is obese and the remainder are of normal body weight or are lean can present some management problems. Ideally, cats should be fed in separate rooms, but this is not always possible. If it is possible, most cats can consume their caloric needs if given at least 4 hours of access to their food daily. Thus the time that cats are separated can be minimized. Moreover, fat cats usually cannot jump very high. Therefore it may be useful to place the food for the lean, healthy cats on an elevated bench or counter that the healthy cats can reach but the obese cat cannot. Alternatively, a hole can be cut into a cardboard box that is large enough to allow the lean cats to enter but small enough to restrict the entry of the overweight or obese cat. The lean cats are then fed in the box.

In addition to reducing the daily caloric intake, every effort should be made to increase the pet's daily energy expenditure by encouraging exercise. Toys that the cat or dog

<sup>\*</sup>Information obtained from manufacturers' published information. Foods with less than ~35% protein calories not listed.

can chase and play with should be encouraged. Laser pointers are particularly useful for encouraging cats to play. Ideally, dogs should receive two 20-minute walks per day. Swimming is an equally effective exercise, particularly for dogs with osteoarthritis. Providing the client with written instructions for weight loss will typically improve both compliance and success. Photographing the patient before institution of the weight reduction program will help clients see the effect of the weight loss on their pet. Institution of reward boards or incentive programs will also increase compliance with the weight reduction program.

Patients on weight reduction programs should be reevaluated every 2 weeks initially. The body weight, BCS, and/or FBMI should be recorded. The dietary history should be reviewed. Ideally, cats should achieve no more than a 2% body weight loss per week. More rapid weight loss in cats increases the risk of hepatic lipidosis. Dogs should achieve a 1% to 2% body weight loss per week. If the rate of weight loss exceeds a 2% body weight loss per week, then the amount of calories fed to the patient should be increased by 10% to 20%. If the patient has not lost any weight, the dietary history should be reevaluated for a source of additional calories and compliance with the weight loss plan confirmed. If no such reasons are found, the daily caloric intake should be further reduced by 10% to 20%.

Once the ideal body condition of the patient has been achieved, the daily caloric intake can be adjusted to maintain an ideal body condition. The patient's regular food may be changed to one formulated for weight maintenance or a light food. The patient should be reevaluated every 2 to 3 months after weight loss to ensure that weight stability is maintained and that the patient is not gaining weight on its new diet regimen.

#### **Prevention**

Ideally, clinicians should focus more on obesity prevention than on treatment because treatment can be very challenging. Energy requirements significantly decrease when the animal has a gonadectomy. Therefore prevention should begin at the time that the pet is neutered. Clients should be counseled about the risk factors of obesity (e.g., male neutered cats, female neutered dogs, inactive and indoor lifestyle, inappropriate feeding practices, energy-dense foods) and the consequences of obesity (e.g., increased incidence of lower urinary tract disease, diabetes mellitus, arthritis, decreased life span). It is important that clients be instructed in both how to feed their pet and how to regularly determine the pet's body condition such that they can maintain the ideal body condition of their pet. Weight education should be reinforced at least annually during the health examination.

#### HYPERLIPIDEMIA

Hyperlipidemia is defined as an increased concentration of triglycerides (hypertriglyceridemia), cholesterol (hypercholesterolemia), or both in the blood. In the fasted state (>10

hours without food), hyperlipidemia is an abnormal finding that represents either accelerated production or delayed degradation of lipoproteins. The lipoproteins function as a carrier system to transport water-insoluble triglycerides and cholesterol through the aqueous environment of blood. Lipoproteins consist of a triglyceride and cholesterol ester core surrounded by a surface layer of cholesterol, phospholipid, and apolipoproteins. The apolipoproteins (A, B, C, and E) are responsible for the structure of the lipoprotein particle, the binding of the particle to cell surface receptors, and the activation of enzymes. There are four major classes of lipoproteins. Each class differs in its lipid and apoprotein content and physicochemical characteristics, including size, density, and electrophoretic mobility. Lipoproteins are categorized according to their buoyant density on ultracentrifugation as chylomicrons, very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), or high-density lipoproteins (HDLs). The buoyant density is inversely proportional to the triglyceride content such that the chylomicrons are composed largely of triglyceride, whereas HDLs have virtually no triglyceride content. The classification system is somewhat arbitrary, and it should be understood that there is significant structural and functional heterogeneity within the classes. In addition, the system is a dynamic one, with one class producing another during its metabolism. Chylomicrons and VLDLs are primarily involved in triglyceride metabolism, whereas HDLs and LDLs are primarily involved in cholesterol metabolism. Dogs and cats are more resistant to the development of atherosclerosis than humans because HDLs predominate in dogs and cats, as opposed to the LDLs that predominate in humans.

#### **Pathophysiology**

After digestion and absorption occur, dietary cholesterol and triglyceride are packaged by the enterocyte into chylomicron particles. The chylomicron particles are secreted into the mesenteric lymph, through which they ultimately reach the systemic circulation via the thoracic duct. As the chylomicrons pass through the adipose and muscle tissue, they are exposed to lipoprotein lipase, an enzyme that is present on the surface of the capillary endothelial cells. After activation by apoprotein C-II, lipoprotein lipase hydrolyzes the triglyceride from the core of the lipoprotein to free fatty acids and glycerol. The free fatty acids diffuse into the adjacent tissue and are either resynthesized into triglycerides and stored (adipocytes) or used for energy by the cell (myocytes and other cells). The activity of lipoprotein lipase is influenced by several factors, including heparin, insulin, glucagon, and thyroid hormone. Depletion of the triglyceride component of the chylomicron alters the surface such that the chylomicron is converted into a chylomicron remnant. The remnant particle is rapidly recognized by specific hepatic receptors and removed from the circulation. Within the hepatocyte the contents of the chylomicron remnant are degraded and utilized. Chylomicrons are present in plasma 30 minutes to 2 hours after consumption of a fat-containing meal, and hydrolysis is normally complete within 6 to 10 hours.

The liver transforms excess free fatty acids that are not directly oxidized for energy into triglycerides. The free fatty acids may originate from residual dietary triglyceride present in chylomicron remnant particles, from endogenous production secondary to surplus dietary carbohydrate, and from excessive endogenous mobilization of free fatty acids. Free fatty acids can be mobilized from adipose tissue by the activation of the intracellular enzyme hormone-sensitive lipase (HSL). HSL hydrolyzes stored triglycerides into free fatty acids and glycerol. Stimulators of HSL include epinephrine, norepinephrine, adrenocorticotropic hormone (ACTH), corticosteroids, growth hormone, and thyroid hormone. In addition, HSL is activated by insulin deficiency. Activation of HSL is a normal physiologic response to provide the body with energy during periods of fasting. In addition, HSL can be inappropriately activated in several pathologic conditions associated with an altered metabolic state.

The triglycerides produced by the hepatocyte are packaged into VLDL particles and subsequently secreted into the bloodstream. VLDL particles are produced continuously by the liver and, in the fasting state, are the main carriers of triglycerides. In addition, VLDL particles are used to export cholesterol from the liver and therefore contain a significant proportion of cholesterol. Analogous to chylomicron metabolism, endothelial lipoprotein lipase hydrolyzes the triglyceride portion of the VLDL particle into free fatty acids and glycerol. The free fatty acids can either be oxidized for energy or reconstituted into triglycerides and stored. Removal of the triglyceride core converts the VLDL particle into a remnant particle, which may be removed and catabolized by the liver. Alternatively, a second endothelial lipase, hepatic lipase, can further remove any residual triglyceride and convert the VLDL remnant particle into an LDL particle.

The LDL particle is a cholesterol and phospholipid—rich entity that functions to transport cholesterol to tissues, where it may be used for membrane synthesis or steroid hormone production. Ultimately, the LDL particle can bind to LDL receptors and is removed by the liver. In addition to VLDL particles, the liver also secretes nascent HDL particles into the circulation. HDL particles act to scavenge excess unesterified cholesterol from the cells and other lipoproteins and return it to the liver for excretion into bile. This process is often referred to as reverse cholesterol transport.

Hypertriglyceridemia can develop secondary to increased chylomicron production (excessive dietary intake of lipid), ineffective clearance of the chylomicron particle, increased VLDL production (excessive dietary intake of lipid and/or carbohydrate, excessive endogenous production or mobilization of lipids), and ineffective clearance of the VLDL particle. Hypercholesterolemia can arise from increased production of the LDL precursor particle (VLDL) or as a result of reduced clearance of the LDL or HDL particle.

#### Classification

Postprandial hyperlipidemia is the most common cause of hyperlipidemia in dogs and cats. It is a normal physiologic manifestation that is due to the production of triglyceride-

#### Causes of Hyperlipidemia in Dogs and Cats

rich chylomicrons and usually resolves within 2 to 10 hours. Pathologic abnormalities in plasma lipids and lipoproteins may be of genetic or familial origin (primary) or arise as a consequence of disease (Box 54-4).

Primary hypertriglyceridemias include the idiopathic hyperlipidemia of Miniature Schnauzers and hyperchylomicronemia of cats. Idiopathic hyperlipidemia of Miniature Schnauzers is characterized by severe hypertriglyceridemia resulting from excessive VLDL particles with or without concurrent hyperchylomicronemia and by mild hypercholesterolemia. The exact mechanism and genetics have not been fully elucidated. Feline familial hyperlipidemia is characterized as a fasting hyperchylomicronemia with a slight increase in VLDL particles. The defect is due to the production of an inactive form of lipoprotein lipase. Idiopathic hyperchylomicronemia has also been observed in dogs. Similar to the situation with the cat, the disease in the dog is characterized by hypertriglyceridemia, hyperchylomicronemia, and normal serum cholesterol concentrations. Idiopathic hypercholesterolemia is rare but has been reported in Doberman Pinschers and Rottweilers. Lipid derangements consist of hypercholesterolemia caused by an increased serum LDL concentration. The etiology of this disorder is unknown.

Diseases associated with secondary hyperlipidemia include endocrine disorders (hypothyroidism, diabetes mellitus, hyperadrenocorticism), nephrotic syndrome, and pancreatitis. Hypothyroidism is the most common cause of hypercholesterolemia in the dog. Hyperlipidemia secondary to hypothyroidism can be attributed to both a decrease in lipid synthesis and degradation (lipid degradation is more severely affected). Decreased lipoprotein lipase activity contributes to the impaired removal of triglyceride-rich lipoproteins. In addition, thyroid hormone deficiency reduces the

biliary excretion of cholesterol. The resultant increase in intrahepatic cholesterol concentration downregulates the hepatic LDL receptor, which increases the concentration of the circulating LDL and HDL cholesterol–rich particles.

Insulin deficiency (diabetes mellitus) reduces the production of lipoprotein lipase, which contributes to decreased clearance of triglyceride-rich lipoproteins. Furthermore, insulin deficiency activates HSL, causing the release of large quantities of free fatty acids into the blood. These free fatty acids are ultimately converted by the liver into triglycerides, packaged into VLDL particles, and secreted back into the circulation. Therefore the hypertriglyceridemia seen with diabetes mellitus is attributed to both a reduction of lipoprotein lipase and increased production and decreased clearance of VLDL particles. Insulin deficiency increases the synthesis of cholesterol in the liver. The increased intrahepatic cholesterol concentration downregulates the hepatocyte LDL receptor, consequently reducing the clearance of circulating LDL and HDL particles, which in turn causes hypercholesterolemia.

The mechanism of hypertriglyceridemia associated with hyperadrenocorticism is probably due to stimulation of HSL with release of free fatty acids into the circulation. Similar to the situation with diabetes mellitus, excess free fatty acids are converted into VLDL particles. In addition, glucocorticoids inhibit lipoprotein lipase activity, thereby reducing the clearance of triglyceride-rich lipoproteins.

#### **Clinical Features**

Waxing-and-waning vomiting, diarrhea, and abdominal discomfort are the most common clinical presentations associated with hypertriglyceridemia (Table 54-4). Severe hypertriglyceridemia (levels exceeding 1000 mg/dl) has been associated with pancreatitis, lipemia retinalis, seizures, cutaneous xanthomas, peripheral nerve paralysis, and behavioral

**TABLE 54-4** 

Clinical Signs and Potential Consequences of Hypertriglyceridemia and Hypercholesterolemia

#### **CLINICAL SIGNS CONSEQUENCES** Seizures Hypertriglyceridemia **Blindness** Seizures Abdominal pain **Pancreatitis** Anorexia Lipid-laden aqueous humor: Vomiting uveitis, blindness Diarrhea Lipemia retinalis Behavioral changes Xanthomas Lipemia retinalis **Uveitis** Xanthoma formation Hypercholesterolemia Peripheral neuropathy Corneal arcus lipoides Horner's syndrome Lipemia retinalis Tibial nerve paralysis Atherosclerosis Radial nerve paralysis

changes. Cutaneous xanthomas, which represent lipid-laden macrophages and foam cells, are the most common manifestation of hypertriglyceridemia in the cat. Severe hypercholesterolemia has been associated with arcus lipoides corneae, lipemia retinalis, and atherosclerosis.

In addition to the clinical manifestations, hypertriglyceridemia may also interfere with the results of several routine biochemical tests (Table 54-5). The degree of interference depends on the specific assay used by the laboratory, the species (canine versus feline), and the severity of the hypertriglyceridemia. In addition, hyperlipidemia may also cause hemolysis, which in turn can interfere with the results of some biochemical assays. Alternatively, hyperbilirubinemia may cause the cholesterol concentration to be falsely lower. These potential alterations in biochemical data must be considered when interpreting results in animals with hyperlipidemia. Fortunately, many laboratories will attempt to clear the hypertriglyceridemia by ultracentrifugation before performing the biochemical assays.

#### Diagnosis

The presence of lipemic serum suggests that the animal is hypertriglyceridemic. Lactescence refers to the opaque and milklike appearance of serum samples that occurs when the elevation of the triglyceride level is sufficient. Animals with lactescent serum typically have triglyceride concentrations that exceed 1000 mg/dl. Conversely, animals that are purely hypercholesterolemic do not exhibit lipemic or lactescent serum because the cholesterol-rich LDL and HDL particles are too small to refract light. Blood samples to confirm hyperlipidemia should be obtained after a fast that lasts at least 12 hours. A serum sample rather than whole blood or plasma should be submitted for assessment. The sample can be refrigerated or frozen for several days without affecting the assays. When assessing the sample for hypertriglyceridemia, the technician should not clear the sample before determination of the triglyceride concentration. Clearing lipemic samples by centrifugation removes chylomicrons, which will artificially lower the triglyceride result. Reference intervals for serum triglyceride concentration are typically 50 to 150 mg/dl for the adult dog and 20 to 110 mg/dl for the adult cat. Reference intervals for serum cholesterol concentration are typically 125 to 300 mg/dl for the adult dog and 95 to 130 mg/dl for the adult cat.

The chylomicron test can be helpful to delineate whether the lipemia is predominantly a chylomicron or a VLDL defect. The test is performed by refrigerating a serum sample for 12 hours. Chylomicrons are less dense than the other particles and hence will float to the top of the sample to form an opaque cream layer over a clear infranatant of serum. If the hypertriglyceridemia is due to excess VLDL particles, the serum sample will remain turbid. Formation of a cream layer over a cloudy serum layer suggests both excess chylomicrons and VLDL particles.

Lipoprotein electrophoresis can be used to distinguish the lipoproteins, and ultracentrifugation can provide a quantitative measurement of each of the lipoprotein classes. However,

**TABLE 54-5**

both of these procedures are time consuming and are not routinely available for clinical application. The activity of lipoprotein lipase can be assessed by the heparin release test. Serum samples for the determination of triglyceride concentrations (and, if possible, lipoprotein concentrations) are obtained before and 15 minutes after the intravenous administration of heparin (90 IU/kg body weight in dogs; 40 IU/kg body weight in cats). Heparin causes the release of lipoprotein lipase from the endothelium and stimulates the hydrolysis of triglycerides. A defect in lipoprotein lipase is suspected if there is no difference between the serum triglyceride concentrations before and after the administration of heparin.

#### **Treatment**

Before therapy is recommended, every attempt should be made to determine whether the hyperlipidemia is primary or secondary to an underlying disease process. Hyperlipidemia secondary to an underlying disorder will typically resolve or improve with correction of the metabolic disturbance. Therefore each animal requires a full history, physical examination, complete blood count, serum biochemistry panel and thyroxine concentrations, and urinalysis. The results of the initial diagnostic evaluation may indicate the need for additional diagnostic tests such as abdominal ultrasound, pancreatic lipase immunoreactivity assay, and evaluation of an ACTH stimulation test. A recommendation to treat hyperlipidemia involves a lifelong commitment by the client and therefore must not be undertaken lightly. In general, severe hypertriglyceridemia (levels exceeding 1000 mg/dl) mandates treatment. In this circumstance catabolic mechanisms can be assumed to be overwhelmed, and the triglyceride level is very sensitive to a small increase from the intestine or liver. The triglyceride levels must be decreased to prevent possible complications, including pancreatitis. In other situations the recommendations will be influenced by additional variables, including the underlying disease process.

A realistic goal of therapy is to reduce the triglyceride concentration to less than 400 mg/dl, even though such a level will still be above the reference interval.

Chylomicrons are produced from dietary fat. Therefore restriction of dietary fat is the cornerstone of therapy for hypertriglyceridemia. The dietary history should be reviewed, and the diet altered to one that contains less than 20% fat on an metabolizable energy (ME) basis for dogs (Table 54-6) or lower if the patient is already on a lower-fat diet. Nutritional management of hypertriglyceridemia in cats is more difficult because of the limited availability of lower-fat commercial therapeutic foods that have less than 24% fat on an ME basis (Table 54-7). Care should be taken when using over-the-counter foods that appear to be lower in fat. Because the proximate analysis that is reported on pet food labels requires only a minimum crude fat percentage to be reported, there is no guarantee that the fat content is not significantly higher. In contrast, therapeutic foods typically provide the average fat content in product guides, which should more accurately reflect the actual fat content of the food. Treats should be restricted to no more than 10% of the daily caloric intake and changed to low-fat commercial varieties. Fruit or brown rice crackers without seasoning are useful alternatives for dogs. In addition to the provision of a lower-fat diet, the absolute caloric intake should be evaluated. If the animal is overweight, caloric restriction is indicated and beneficial because it decreases the production of VLDL particles from excess dietary energy. The plasma triglyceride concentration should be reevaluated after 8 weeks of a lower-fat diet. If the reduction in triglyceride concentration is less than ideal, the dietary history should be reevaluated to ensure that there are no extra fat calories from treats, no access to other pet foods, and no additional family members or neighbors who are inadvertently providing the animal with dietary fat. In addition, the medical record should be reviewed to ensure the exclusion of underlying disorders that would contribute to

<sup>\*</sup>Information obtained from manufacturers' published information. Foods with less than 24% fat calories are listed.

hypertriglyceridemia. If the lower-fat commercial foods are not sufficient to control the hypertriglyceridemia, then a complete and balanced fat-restricted (10% to 14% ME for dogs, 15% to 19% ME for cats) home-prepared recipe can be formulated specifically for the animal using online software (such as at balanceit.com) or through a veterinary nutritionist (see acvn.org). Diets rich in omega-3 fatty acids have been suggested to improve hypertriglyceridemia in humans by decreasing the production of VLDL particles. In addition, fish oils are poor substrates for triglyceridesynthesizing enzymes, and their use leads to the formation of triglyceride-poor VLDL particles. Some clinicians have recommended fish oil rich in long chain omega-3 fatty acids (i.e., EPA and DHA) in the amount of 200 to 220 mg/kg body weight/day to assist in the management of hypertriglyceridemia, especially in dogs refractory or incompletely responsive to dietary fat restriction.

Treatment with drugs, all of which have the potential for toxicity, should be undertaken with particular care. In general, drugs should not be used in animals whose scrum triglyceride concentration is less than 500 mg/dl. Several classes of drugs are used to treat hypertriglyceridemia in humans; however, there are few reports of their use in cats and dogs. Until there are further studies evaluating the dose, effect, and toxicity, drug therapy is indicated only in animals that have clinical signs associated with severe elevations in

triglyceride concentrations that cannot be ameliorated by dietary therapy, which is very uncommon in one of the author's (SJD) clinical experience.

Niacin (100 mg/day in dogs) reduces serum triglyceride concentrations by decreasing fatty acid release from adipocytes and reducing the production of VLDL particles. Adverse effects are frequent, mainly because of the associated release of the prostaglandin prostacyclin, and include vomiting, diarrhea, erythema, pruritus, and abnormalities in liver function tests. Fibric acid derivatives (clofibrate, bezafibrate, gemfibrozil, ciprofibrate, fenofibrate) lower plasma triglyceride concentrations by stimulating lipoprotein lipase activity, in addition to reducing the free fatty acid concentration, which decreases the substrate for VLDL synthesis. In humans the fibrates generally lower plasma triglyceride concentrations by 20% to 40%. Gemfibrozil has been used in the dog (200 mg/day) and cat (10 mg/kg q12h). Reported adverse effects include abdominal pain, vomiting, diarrhea, and abnormal liver function tests. The statins (lovastatin, simvastatin, pravastatin, fluvastatin, cerivastatin, atorvastatin) are hydroxymethyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors and therefore primarily suppress cholesterol metabolism. As a consequence of lower intracellular cholesterol concentrations, the hepatic LDL receptor is upregulated, thereby increasing the removal and clearance of LDL (VLDL remnant particles) from the circulation. In addition,

<sup>\*</sup>Information obtained from manufacturers' published information. Foods with less than 20% fat calories are listed.

the statins decrease hepatic production of VLDL. In humans the statins can lower triglyceride concentrations by 10% to 15%. Adverse effects include lethargy, diarrhea, muscle pain, and hepatotoxicity.

Hypercholesterolemia is most likely associated with the presence of an underlying disease and generally resolves with control of the altered metabolic state. Unlike the situation with humans, hypercholesterolemia rarely poses a health risk to the dog or cat. Specific therapy is indicated only for those animals with a prolonged marked increase in the serum cholesterol concentration (i.e., more than 800 mg/dl) that may be associated with the development of atherosclerosis. Nutritional therapy with a lower-fat diet is the initial treatment of choice for severe hypercholesterolemia. The addition of soluble fiber to the diet may also help to reduce plasma cholesterol concentrations by as much as 10%. Soluble fiber interferes with the enteric reabsorption of bile acids. Consequently, the liver uses cholesterol to increase the synthesis of bile acids.

Pharmacologic agents that can be considered for the management of severe hypercholesterolemia include bile acid sequestrates, HMG-CoA reductase inhibitors, and probucol. Bile acid sequestrates are ion exchange resins that interrupt the enterohepatic circulation of bile acids. Decreased reabsorption of bile acids stimulates the liver to synthesize bile acids, utilizing intrahepatic cholesterol. Depletion of intrahepatic cholesterol stores stimulates the hepatic LDL receptor to increase the removal of LDL and HDL particles from the circulation. Cholestyramine (1 to 2 g, administered orally q12h) is effective for lowering cholesterol concentrations; however, its use has been associated with constipation, it interferes with the absorption of several oral medications, and it may increase hepatic VLDL synthesis, resulting in an increase in plasma triglyceride concentrations. It may also increase the dietary requirement for sulfur amino acids because they serve as precursors for taurine synthesis in the dog, which conjugates bile acids exclusively with taurine. In cats the requirement for dietary taurine may be similarly increased. HMG-CoA reductase is the rate-limiting enzyme for cholesterol synthesis. The HMG-CoA reductase inhibitors (lovastatin, simvastatin, pravastatin, fluvastatin, cerivastatin, and atorvastatin) are the most potent cholesterol-lowering agents and in humans may reduce cholesterol concentrations by 20% to 40%. Lovastatin (10 to 20 mg, administered orally q24h) may be tried in dogs with persistent, severe idiopathic hypercholesterolemia that does not respond to diet alone. Potential adverse effects include lethargy, diarrhea, muscle pain, and hepatotoxicity. Lovastatin should not be administered to dogs with hepatic disease. Probucol is a cholesterollowering agent whose mechanism of action is not completely clear. Probucol is not widely recommended for the management of hypercholesterolemia because its effect on lowering cholesterol concentrations is variable and it has been associated with the development of arrhythmias.

#### CHAPTER OUTLINE

HYPERNATREMIA
HYPONATREMIA
HYPERKALEMIA
HYPOKALEMIA
HYPERCALCEMIA
HYPOCALCEMIA
HYPERPHOSPHATEMIA
HYPOPHOSPHATEMIA
HYPOMAGNESEMIA
HYPERMAGNESEMIA

#### **HYPERNATREMIA**

#### **Etiology**

Hypernatremia exists if the serum sodium concentration exceeds 160 mEq/L, although reference ranges may vary between laboratories. It most commonly develops after water loss exceeds sodium loss (Box 55-1). The water loss may be pure (i.e., not accompanied by a loss of electrolytes, such as that which occurs with diabetes insipidus), or it may be hypotonic (i.e., loss of both water and sodium but with the water loss predominating, such as that which occurs with gastrointestinal fluid loss and renal failure). Insufficient water intake or an abnormal thirst mechanism are usually facets of an excessive water loss. Rarely, hypernatremia may occur in animals with hypodipsia caused by neurologic disease, an abnormal thirst mechanism, or defective osmoregulation of vasopressin release.

Less commonly, hypernatremia develops after sodium retention, such as that which occurs with iatrogenic sodium overload or primary hyperaldosteronism. Primary hyperaldosteronism is caused by an aldosterone-secreting adrenal tumor or idiopathic bilateral adrenal hyperplasia but is rare in dogs and cats. Increased serum aldosterone concentrations cause variable hypernatremia, hypokalemia, and systemic hypertension.

#### **Clinical Features**

Clinical signs of hypernatremia originate in the central nervous system (CNS) and include lethargy, weakness, muscle fasciculations, disorientation, behavioral changes, ataxia, seizures, stupor, and coma. Clinical signs typically become apparent when the plasma osmolality exceeds 350 mOsm/kg (serum sodium concentration of greater than 170 mEq/L). Clinical signs are caused by neuronal dehydration. Hypernatremia and hyperosmolality cause fluid to shift from the intracellular to the extracellular space. As the brain shrinks, meningeal vessels are damaged and torn, causing hemorrhage, hematoma, venous thrombosis, infarction of cerebral vessels, and ischemia. This gradient flow of water from the intracellular to the extracellular compartment often maintains adequate skin turgor and gives a false impression of hydration, even though the animal has experienced a detrimental loss of fluid.

The severity of clinical signs is related to the absolute increase in serum sodium concentration and especially the rapidity of onset of hypernatremia and hyperosmolality. Clinical signs usually do not develop until the serum sodium concentration approaches 170 mEq/L. If hypernatremia is rapid in onset, clinical signs may develop at a lower sodium concentration, and vice versa. With a gradual increase in the serum sodium concentration, the cells in the CNS can produce osmotically active solutes (idiogenic osmoles) intracellularly to reestablish osmotic equilibration between the extracellular and intracellular compartments, thereby minimizing cell shrinkage.

#### Diagnosis

Measurement of the serum sodium concentration identifies hypernatremia. After it has been identified, the underlying cause should be sought. Careful evaluation of the history, physical examination findings, and results of routine clinical pathologic tests (i.e., complete blood count [CBC], serum biochemistry panel, urinalysis) usually yields clues to the cause. Evaluation of the urine specific gravity is especially helpful. Hypernatremia and hyperosmolality stimulate the release of vasopressin, resulting in hypersthenuria. A urine

Modified from DiBartola SP: Disorders of sodium and water: hypernatremia and hyponatremia. In DiBartola SP, editor: *Fluid*, electrolyte and acid-base disorders in small animal practice, ed 3, St Louis, 2006, Saunders/Elsevier. specific gravity of less than 1.008 in a dog or cat with hypernatremia is consistent with central or nephrogenic diabetes insipidus. A urine specific gravity of more than 1.030 in a dog and 1.035 in a cat implies a normal vasopressin–renal tubular axis and indicates the existence of sodium retention, primary hypodipsia-adipsia, or gastrointestinal or insensible water loss. A urine specific gravity of between 1.008 and 1.030 (dog) or of 1.035 (cat) indicates the presence of partial vasopressin deficiency or an impaired renal tubular response to vasopressin, most likely secondary to a primary renal disorder.

#### **Treatment**

The goal in treating hypernatremia is to restore the extracellular fluid (ECF) volume to normal and correct water deficits at a fluid rate that avoids significant complications and to identify and correct the underlying cause of the hypernatremia. The initial priority is to restore ECF volume to normal. In animals with modest volume contraction (e.g., tachycardia, dry mucous membranes, slow skin turgor), fluid deficits should be corrected with 0.45% saline supplemented with an appropriate amount of potassium (Table 55-1). With severe dehydration 0.9% saline solution, plasma, or whole blood should be used to expand vascular volume. In deficit replacement rapid administration of fluids is contraindicated unless there are signs of significant hypovolemia. Any fluid should be administered in a volume only large enough to correct hypovolemia. Worsening neurologic status or sudden onset of seizures during fluid therapy is generally indicative of cerebral edema and the need for hypertonic saline solution or mannitol therapy. Once ECF deficits have been replaced, the serum sodium (Na) concentration should be reevaluated and water deficits corrected if hypernatremia persists. An approximation of the water deficit in liters may be calculated using the following formula:

#### $0.3 \times \text{body weight (kg)} \times [(\text{measured Na}^+ - 140)/140]$

Because the brain adjusts to hypertonicity by increasing the intracellular solute content via the accumulation of "idiogenic osmoles," the rapid repletion of body water with ECF dilution causes translocation of water into cells and may

<sup>\*</sup> Total hourly potassium administration should not exceed 0.5 mEq/kg body weight.

<sup>\*</sup> Common causes.

cause cerebral edema. If slower water repletion is undertaken, brain cells lose the accumulated intracellular solutes and osmotic equilibration can occur without cell swelling.

Maintenance crystalloid solutions (e.g., half-strength [0.45%] saline solution with 2.5% dextrose or half-strength lactated Ringer's solution with 2.5% dextrose) should be used to correct the water deficit in hypernatremic animals with normal perfusion and hydration and should also be used in dehydrated animals with persistent hypernatremia after the correction of fluid deficits. D₅W solution can be substituted for maintenance crystalloid solutions if the hypernatremia does not abate after 12 to 24 hours of fluid therapy.

Oral fluid administration is preferable for correcting water deficits, with fluid administered through an intravenous (IV) route if oral administration is not possible. The water deficit should be replaced slowly. Approximately 50% of the water deficit should be corrected in the first 24 hours, with the remainder corrected over the ensuing 24 to 48 hours. The serum sodium concentration should decline slowly, preferably at a rate of less than 1 mEq/L/hour. A gradual reduction in the serum sodium concentration minimizes the fluid shift from the extracellular to the intracellular compartment, thereby minimizing neuronal cell swelling and cerebral edema and increasing intracranial pressure. A deterioration in CNS status after the start of fluid therapy indicates the presence of cerebral edema and the immediate need to reduce the rate of fluid administration. Frequent monitoring of serum electrolyte concentrations, with appropriate adjustments in the type of fluid administered and rate of fluid administration, is important in the successful management of hypernatremia.

On rare occasions a hypernatremic animal presents with an increase in the ECF volume. Such animals are difficult to treat. The goal is to lower the serum sodium concentration without exacerbating an increase in the ECF volume and causing pulmonary congestion and edema. To slowly correct hypernatremia in these animals, the clinician should administer loop diuretics (e.g., furosemide, 1 to 2 mg/kg orally or intravenously q8-12h) to promote sodium loss in the urine, and this is done in conjunction with the judicious administration of  $D_{\bar{5}}W$ .

#### HYPONATREMIA

#### Etiology

Hyponatremia is present if the serum sodium concentration is less than 140 mEq/L, although reference ranges may vary between laboratories. It can result from excessive sodium loss, primarily through the kidney, or from increased water conservation, or both. The latter condition may be an appropriate response to a reduction in the ECF volume or may be inappropriate (e.g., syndrome of inappropriate antidiuretic hormone secretion). In most cases hyponatremia results from abnormalities in water balance (principally a defect in renal water excretion) rather than from abnormalities in

sodium balance. Causes of hyponatremia in dogs and cats are listed in Box 55-2.

Hyponatremia must be differentiated from pseudohyponatremia, which is a decrease in the serum sodium concentration as a result of laboratory methodology in the presence of normal plasma osmolality. Pseudohyponatremia occurs in the presence of hyperlipidemia or severe hyperproteinemia. An increase in the concentration of triglycerides or proteins in plasma reduces the sodium concentration in the total plasma volume, but the sodium concentration in plasma water remains the same. Methods that measure the amount of sodium in a specific volume of plasma (e.g., flame photometry) result in falsely low sodium values, whereas methodologies that determine the sodium concentration in the aqueous phase of plasma (e.g., direct potentiometry using ion-selective electrodes) yield an accurate sodium value. Pseudohyponatremia can usually be identified if the method used to measure the sodium concentration is known, a blood

sample is examined for the presence of gross lipemia, and a CBC and serum biochemistry panel are performed.

Hyponatremia may also occur after there is an increase in the concentration of osmotically active solutes (e.g., glucose, mannitol) in the ECF. An increase in the concentration of osmotically active solutes in the ECF causes a fluid shift from the intracellular to the extracellular compartment and a corresponding decrease in the serum sodium concentration. For example, the serum sodium concentration decreases approximately 1.6 mEq/L for every 100 mg/dl increase in the serum glucose concentration, and this decrease may become more severe when the blood glucose concentration exceeds 500 mg/ dl. Estimation of the plasma osmolality is helpful in differentiating the cause of hyponatremia. Hyponatremia is usually associated with hyposmolality (less than 290 mOsm/kg), whereas pseudohyponatremia is associated with normal plasma osmolality, and hyponatremia caused by an increase in osmotically active solutes in the ECF is associated with hyperosmolality. Plasma osmolality can be estimated using the following formula:

Plasma osmolality (mOsm/kg) =  $(2 \times Na [mEq/L]) +$ 

$$\frac{Glucose~(mg/dl)}{18} + \frac{Urea~nitrogen~(mg/dl)}{2.8}$$

Normal plasma osmolality in dogs and cats is approximately 280 to 310 mOsm/kg.

#### **Clinical Features**

Clinical signs of hyponatremia include lethargy, anorexia, vomiting, weakness, muscle fasciculations, disorientation, seizures, and coma. CNS signs are the most worrisome and develop as changes in plasma osmolality cause fluid to shift from the extracellular to the intracellular space, resulting in neuronal swelling and lysis. The onset and severity of clinical signs depend on the rapidity with which the hyponatremia develops as well as on the degree of hyponatremia. The more chronic the hyponatremia and the more slowly it develops, the more capable the brain is of compensating for changes in osmolality through the loss of potassium and organic osmolytes from cells. Clinical signs develop when the decrease in plasma osmolality occurs faster than the brain's defense mechanisms can counter the influx of water into the neurons.

#### Diagnosis

Hyponatremia is readily evident from measurement of serum electrolyte concentrations. However, hyponatremia must be differentiated from pseudohyponatremia (discussed in a previous section). Hyponatremia is not a diagnosis per se but rather a manifestation of an underlying disorder. As such, a diagnostic evaluation to identify the cause, as well as appropriate therapy to correct the hyponatremia, should be initiated. In most dogs and cats the cause of hyponatremia is readily apparent after evaluation of the history, physical examination findings, CBC, serum biochemistry panel, and urinalysis findings, but further diagnostic tests may be neces-

sary. Careful assessment of the urine specific gravity; the hydration status of the animal; and, if necessary, the fractional excretion of sodium (FE<sub>Na</sub>) help localize the problem (Fig. 55-1). The FE<sub>Na</sub> can be determined by first measuring the urine ( $U_{Na}$ ) and plasma ( $P_{Na}$ ) sodium and urine ( $U_{Cr}$ ) and plasma ( $P_{Cr}$ ) creatinine concentrations and then applying the following formula:

$$FE_{Na} = (U_{Na}/P_{Na}) \times (P_{Cr}/U_{Cr}) \times 100$$

#### **Treatment**

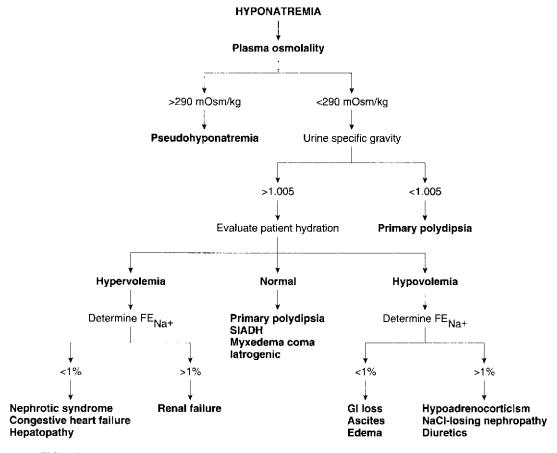

The goals of therapy are to treat the underlying disease and, if necessary, to increase the serum sodium concentration and plasma osmolality. The goal of treatment directed at the hyponatremia is to correct body water osmolality and restore cell volume to normal by raising the ratio of sodium to water in ECF using IV fluid therapy, water restriction, or both. The increase in ECF osmolality draws water from cells and therefore reduces their volume. The approach to treatment and the type of fluid used depend on the underlying etiology, the severity of the hyponatremia, and the presence or absence of clinical signs (Table 55-2). Chronic hyponatremia in an asymptomatic animal is best treated conservatively. Lactated Ringer's or Ringer's solution can be used for mild hyponatremia (serum sodium concentration of more than 135 mEq/ L) and physiologic saline solution for more severe hyponatremia (serum sodium concentration of less than 135 mEq/ L). Physiologic saline solution is typically used in symptomatic animals with severe hyponatremia.

Fluid and electrolyte balance should gradually be restored over 24 to 48 hours, with periodic assessment of serum electrolyte concentrations. The more acute and severe the hyponatremia, the more slowly the serum sodium concentration should be corrected. A rapid increase in the serum sodium concentration to levels greater than 125 mEq/L is potentially dangerous and should be avoided in animals with acute, severe hyponatremia (serum sodium concentration of less than 120 mEq/L) and neurologic signs. For these animals the serum sodium concentration should be gradually increased to 125 mEq/L or higher over 6 to 8 hours. Because loss of brain solute represents one of the compensatory mechanisms for preserving brain cell volume during dilutional states, an increase in serum sodium concentration toward normal is relatively hypertonic to brain cells that are partially depleted of solute as a result of hyponatremia. Consequently, raising the serum sodium concentration rapidly to greater than 125 mEq/L can cause CNS damage. Dietary sodium restriction (e.g., Prescription Diet h/d, Hill's Pet Products) and diuretic therapy should be considered in edematous animals.

#### HYPERKALEMIA

#### Etiology

Hyperkalemia is present if the serum potassium concentration exceeds 5.5 mEq/L, although reference ranges may vary

**FIG 55-1**Diagnostic approach to hyponatremia. *FE*<sub>No</sub>, Fractional excretion of sodium. (Adapted from DiBartola SP: Hyponatremia, *Vet Clin North Am* 19:215, 1989.)

between laboratories. Hyperkalemia can develop after an increased potassium intake (uncommon), after a compartmental shift in potassium from the intracellular to extracellular space (uncommon), or as a result of impaired potassium excretion in the urine (common; Box 55-3). Impaired urinary excretion of potassium is usually caused by renal dysfunction or hypoadrenocorticism. Iatrogenic-induced hyperkalemia is also common in dogs and cats. Pseudohyperkalemia refers to an increase in potassium in vitro and can occur in the setting of severe hypernatremia (if dry reagent methodologies are used), leukocytosis (white blood cell count of more than 100,000/ $\mu$ l), and thrombocytosis (more than 1 × 10<sup>6</sup>/ μl); if the blood specimen has been obtained from fluid lines or catheters contaminated with potassium-containing fluids; and in the setting of hemolysis in Akitas (and possibly Shiba Inus and Kindos) and in English Springer Spaniels with phosphofructokinase deficiency.

#### **Clinical Features**

The clinical manifestations of hyperkalemia reflect changes in cell membrane excitability and the magnitude and rapidity of onset of hyperkalemia. Mild-to-moderate hyperkalemia (serum potassium concentration of less than 6.5 mEq/L) is typically asymptomatic. Generalized skeletal muscle weak-

ness develops as the hyperkalemia worsens. Weakness occurs after a hyperkalemia-induced decrease in the resting cell membrane potential to the level of the threshold potential, thereby impairing repolarization and subsequent cell excitation. The most prominent manifestations of hyperkalemia are cardiac in nature. Hyperkalemia causes decreased myocardial excitability, an increased myocardial refractory period, and slowed conduction, effects that may cause potentially life-threatening cardiac rhythm disturbances (Box 55-4).

#### Diagnosis

Measurement of the serum potassium concentration or electrocardiography can identify hyperkalemia. Once it has been identified, a careful review of the history, physical findings, CBC, serum biochemistry panel, and urinalysis usually yields clues to the cause. The most common causes for hyperkalemia in the dog and cat are iatrogenic, most notably excessive potassium administration in IV fluids; renal dysfunction, especially acute oliguric-anuric renal failure, urethral obstruction (tomcats), and rupture within the urinary system leading to uroabdomen; and hypoadrenocorticism. It can be a diagnostic challenge to differentiate renal dysfunction from hypoadrenocorticism because both disorders can result in a similar clinical picture. An adrenocorticotropic

hyperkalemia should be initiated if the serum potassium concentration is greater than 7 mEq/L or if pronounced cardiac toxicity (i.e., complete heart block, premature ventricular contractions, arrhythmias) is identified on an electrocardiogram (ECG; Table 55-3). The rapid institution of therapy in animals with marked hyperkalemia could mean the difference between life and death. The goal of symptomatic therapy is to reverse the cardiotoxic effects of hyperkalemia and, if possible, reestablish normokalemia. Asymptomatic animals with normal urine output and chronic hyperkalemia of less than 7 mEq/L may not require immediate treatment, but a search for the underlying cause should be initiated.

IV fluid administration in amounts designed to correct fluid deficits and cause volume expansion rehydrates the animal, improves renal perfusion and potassium excretion, and dilutes the blood potassium concentration. Physiologic saline solution is the fluid of choice for this purpose. Potassium-containing fluids (e.g., lactated Ringer's solution) can be used if physiologic saline solution is not available because the low potassium concentration in these fluids (see Table 55-2) in relation to that in blood will still have a dilutional effect on the blood potassium concentration. Dextrose can be added to the fluids to make a 5% to 10% dextrosecontaining solution, or 1 to 2 ml/kg of 50% dextrose can be administered by slow IV bolus. Dextrose stimulates insulin secretion, which in turn promotes the movement of glucose and potassium from the extracellular to the intracellular space. Fluids containing more than 5% dextrose should be given into a central vein to minimize the risk of phlebitis.

Rarely, additional therapy may be required to block the cardiotoxic effects of hyperkalemia (see Table 55-3). Sodium bicarbonate and regular insulin given with dextrose act to shift potassium from the extracellular to the intracellular space. IV calcium infusions block the effects of hyperkalemia on cell membranes but do not lower the blood potassium concentration. These therapies constitute aggressive, short-term, life-saving measures that can reestablish normal cardiac conduction until more conventional therapy (i.e., IV fluids) has the time to become effective.

**TABLE 55-3** 

Treatment Options for Hyperkalemia in the Dog and Cat

TREATMENT	DOSAGE	ROUTE OF ADMINISTRATION	DURATION OF EFFECT
Physiologic saline	≥60-100 ml/kg/day	IV	Hours

	2 g dextrose/U insulin administered	IV	Monitor blood glucose
Sodium bicarbonate	1-2 mEq/kg	IV, slow bolus	Hours
10% Calcium gluconate	2-10 ml	IV, slow bolus	30-60 min. Monitor heart

#### HYPOKALEMIA

#### Etiology

Hypokalemia is present when the serum potassium concentration is less than 4.0 mEq/L, although reference ranges may vary between laboratories. Hypokalemia can develop after decreased dietary potassium intake (uncommon), translocation of potassium from the ECF to the intracellular fluid (common), or increased potassium loss in urine or gastrointestinal secretions (common; Box 55-5). Iatrogenic hypokalemia is also common in dogs and cats. Pseudohypokalemia is uncommon and depends on the method used to measure the serum potassium concentration. Hyperlipidemia, hyperproteinemia (more than 10 g/dl), hyperglycemia (more than 750 mg/dl), and azotemia (urea nitrogen concentration of more than 115 mg/dl) can potentially cause pseudohypokalemia.

ECF, Extracellular fluid; ICF, intracellular fluid. \*Common causes.

#### **Clinical Features**

Most dogs and cats with mild to moderate hypokalemia (i.e., 3.0 to 4.0 mEq/L) are asymptomatic. Clinically severe hypokalemia primarily affects the neuromuscular and cardiovascular systems, owing to the hypokalemia-induced initial hyperpolarization followed by hypopolarization of cell membranes. The most common clinical sign of hypokalemia is generalized skeletal muscle weakness. In cats ventroflexion of the neck (see Chapter 72), forelimb hypermetria, and a broad-based hindlimb stance may be observed. The timing of the onset of hypokalemia-induced weakness is extremely variable among animals. Cats seem more susceptible than dogs to the deleterious effects of hypokalemia. In dogs signs may not be evident until the serum potassium concentration is less than 2.5 mEq/L, whereas in cats signs can be seen when the serum potassium concentration is between 3 and 3.5 mEa/L.

Cardiac consequences of hypokalemia include decreased myocardial contractility, decreased cardiac output, and disturbances in cardiac rhythm. Cardiac disturbances assume a variable clinical expression, often evidenced only by electrocardigraphy (see Box 55-4). Other metabolic effects of hypokalemia include hypokalemic nephropathy, which is characterized by chronic tubulointerstitial nephritis, impaired renal function, and azotemia and manifested clinically as polyuria, polydipsia, and impaired urine concentrating capability; hypokalemic polymyopathy, which is characterized by increased serum creatine kinase activity and electromyographic abnormalities; and paralytic ileus, manifested clinically as abdominal distention, anorexia, vomiting, and constipation. Hypokalemic nephropathy and polymyopathy are most notable in cats.

#### **Diagnosis**

Measurement of the serum potassium concentration identifies hypokalemia. Once it has been identified, a careful review of the history, physical findings, CBC, serum biochemistry panel, and urinalysis findings usually provides clues to the cause (see Box 55-5). If the cause is not readily apparent after review of this information, other, less likely causes for hypokalemia should be considered, such as renal tubular acidosis or another renal potassium-wasting disorder, primary hyperaldosteronism, and hypomagnesemia. To help differentiate renal and nonrenal sources of potassium loss, the clinician may need to determine the fractional excretion of potassium determined on the basis of a single urine and serum potassium and creatinine concentration or determine 24-hour urine potassium excretion (see Chapter 42).

#### **Treatment**

Therapy is indicated if the serum potassium concentration is less than 3 mEq/L, if clinical signs related to hypokalemia are present, or if a serum potassium loss is anticipated (e.g., insulin therapy in diabetic ketoacidosis [DKA]) and the animal's ability to compensate for the loss is impaired. The goal of therapy is to reestablish and maintain normokalemia without inducing hyperkalemia.

Potassium supplements should be given orally whenever possible. Oral potassium supplements come in the form of elixirs, wax-matrix tablets, and microencapsulated slowrelease formulations. Problems with oral preparations include poor palatability, which can be minimized by mixing them with food, and gastrointestinal tract irritation, which may cause vomiting, diarrhea, and melena. Two products that are well accepted by most dogs and cats and that have minimal gastrointestinal tract side effects are potassium gluconate elixir (Kaon Elixir, Adria Laboratories) and potassium gluconate prepared in a palatable protein base (Tumil-K, Virbac). The recommended dose for these products is 2.2 mEq of potassium per 100 calories of required energy intake per day or 2 mEq of potassium per 4.5 kg of body weight twice a day. Subsequent adjustments in dosage are made on the basis of clinical response and serum potassium concentrations. Bananas are also a good source of potassium. Ten inches (25 cm) of banana contains approximately 10 mEq of potassium.

Parenteral potassium supplementation is indicated if oral administration is not possible (e.g., vomiting, anorexia). Potassium chloride is the compound most commonly used, in part to help promote chloride as well as potassium repletion. IV administration is preferred, although potassium chloride can be given subcutaneously as long as the concentration of potassium does not exceed 30 mEq/L. In dogs and cats with normal renal function, the maintenance amount of potassium supplementation is approximately 20 mEq/L of fluids. The initial amount of potassium added to fluids depends on the animal's serum potassium concentration (see Table 55-1) and the amount of potassium already present in the fluids (see Table 55-2). The rate of IV potassium administration should not exceed 0.5 mEq/kg/hour.

It is difficult to estimate the amount of potassium required to reestablish normal potassium balance on the basis of the serum potassium concentration because potassium is primarily an intracellular cation. As such, serial measurement of the serum potassium concentration is important during treatment and should initially be done every 6 to 12 hours depending on the severity of the hypokalemia and the rate of potassium administration. Adjustments in potassium therapy should be made accordingly, with the goal of establishing a normal serum potassium concentration and then maintaining the serum potassium concentration in the normal range as treatment is withdrawn. Clinical signs of hypokalemia usually resolve within 1 to 5 days after correction of hypokalemia. Depending on the underlying cause, long-term oral potassium supplementation may be required to prevent recurrence of hypokalemia.

#### HYPERCALCEMIA

#### **Identification**

Hypercalcemia is present if the serum calcium concentration is greater than 12 mg/dl or the serum ionized calcium concentration is greater than 1.45 mmol/L, although reference

ranges may vary between laboratories. The serum total and ionized calcium concentration is higher in puppies than in adult dogs. A mild increase in the serum total calcium (i.e., less than 13 mg/dl), ionized calcium (i.e., less than 1.55 mmol/L), and phosphorus (i.e., less than 10 mg/dl) concentrations in a clinically healthy puppy, together with an increase in the serum alkaline phosphatase activity and normal urea nitrogen and creatinine concentrations, should be considered normal. The serum total calcium concentration does not fluctuate with age in cats, but the serum ionized calcium concentration may be higher (less than 0.1 mmol/L) in cats younger than 2 years of age compared with results in older cats.

Most automated and in-house serum chemistry analyzers measure the total serum calcium concentration, which consists of biologically active, ionized calcium (55%); proteinbound calcium (35%); and calcium complexes (10%). A drawback to this is that alterations in the plasma protein concentration may alter the total serum calcium concentration, yet the ionized calcium concentration remains normal. For this reason the serum albumin and total protein concentrations should be measured when determining the total serum calcium concentration in the dog. Simple quantitative changes in the albumin and total plasma proteins do not cause hypocalcemia or hypercalcemia in dogs, even though the total serum calcium levels may appear to be low or high on the biochemistry panel. The following formulas have been used to estimate the total serum calcium concentration in dogs with hypoalbuminemia or hypoproteinemia:

Adjusted calcium (mg/dl) = Serum calcium (mg/dl) - Serum albumin (g/dl) + 3.5

or

Adjusted calcium (mg/dl) = Serum calcium (mg/dl) –  $(0.4 \times \text{Serum total protein } [g/dl]) + 3.3$ 

The formulas are not used in dogs younger than 24 weeks of age, because high values may be obtained, nor are they used in cats, because there is no linear relationship between serum total calcium and serum albumin and total protein concentration in cats. These formulas yield a rough estimate of the total serum calcium concentration and were developed without verification by serum ionized calcium measurements. Subsequent studies identified a poor correlation between the adjusted total calcium results and the corresponding serum ionized calcium concentration, suggesting that adjusted total serum calcium concentrations are not reliable indicators of calcium homeostasis.

The biologically active, ionized fraction of calcium can be determined directly, which bypasses the influence of plasma proteins on the total serum calcium concentration. Ionized calcium measurements are generally superior to serum total calcium measurements for assessing calcium in dogs and cats. Automated equipment that uses a calcium ion-selective electrode allows accurate measurement of ionized calcium in blood, plasma, or serum. Ionized calcium results can be affected by many variables, including method of sample

collection (samples collected anaerobically provide more precise results); the amount and type of heparin, if used (may underestimate or overestimate ionized calcium results); and change in sample pH (ionized calcium increases as pH decreases). Protocols established by the clinical chemistry laboratory for submitting blood samples for ionized calcium determination should be followed to ensure accurate results.

#### **Etiology**

Hypercalcemia is uncommon in dogs and cats. Persistent hypercalcemia usually results from increased calcium resorption from bone or kidney or increased calcium absorption from the gastrointestinal tract. Humoral hypercalcemia of malignancy (HHM), the most common cause of hypercalcemia, occurs when the tumor produces substances that promote osteoclastic activity and renal calcium reabsorption. These substances include parathyroid hormone (PTH); parathyroid hormone-related peptide (PTHrP); 1,25dihydroxyvitamin D; cytokines, such as interleukin-1 and tumor necrosis factor; prostaglandins; and humoral factors that stimulate renal 1-α-hydroxylase. Tumors may also induce hypercalcemia by local osteolytic activity after they metastasize to bone. Less commonly, hypercalcemia develops from impaired loss of calcium from the serum (e.g., reduced glomerular filtration) or reduced plasma volume (e.g., dehydration).

The list of differential diagnoses for hypercalcemia is relatively short in dogs and cats (see Table 50-2). In the dog HHM (especially lymphoma), hypoadrenocorticism, chronic renal failure, hypervitaminosis D, and primary hyperparathyroidism are the most common diagnoses. In the cat idiopathic hypercalcemia, hypercalcemia of malignancy (especially lymphoma and squamous cell carcinoma), chronic renal failure, and primary hyperparathyroidism are the most common diagnoses. Calcium oxalate urolithiasis and consumption of acidifying diets are commonly identified in cats with hypercalcemia, but their role, if any, in causing the disorder is unknown.

Hypercalcemia can develop in dogs and cats with chronic and, less commonly, acute renal failure. The pathogenesis of hypercalcemia associated with renal failure is complicated. The development of autonomously functioning parathyroid glands or an alteration of the set point for PTH secretion after the prolonged stimulation of renal secondary hyperparathyroidism, decreased PTH degradation by renal tubular cells, increased PTH-mediated intestinal absorption of calcium, increased PTH-mediated bone resorption, decreased renal excretion of calcium, and increased protein-bound or complexed fractions of calcium are believed to contribute to the hypercalcemia of renal failure. Prolonged hypercalcemia, especially in conjunction with concurrent high-normal to increased serum phosphorus concentration, can also cause renal insufficiency and azotemia. Determining whether the renal failure is primary or secondary in a dog with hypercalcemia, hyperphosphatemia, and azotemia poses an interesting diagnostic challenge (see the diagnosis section).

#### **Clinical Features**

Although all tissues can be affected by hypercalcemia, the neuromuscular, gastrointestinal, renal, and cardiac systems are the most important clinically. Secondary nephrogenic diabetes insipidus, loss of the renal concentration gradient, and metastatic mineralization of the kidney cause polyuria and polydipsia. Decreased excitability of the central and peripheral nervous systems occurring in conjunction with decreased excitability of gastrointestinal smooth muscle causes lethargy, anorexia, vomiting, constipation, weakness, and (rarely) seizures. In rare instances cardiac arrhythmias may develop in animals with severe hypercalcemia (i.e., more than 18 mg/dl). Prolongation of the PR interval and shortening of the QT interval may be found on electrocardiographic readings recorded in animals with milder hypercalcemia.

Clinical signs are often absent with mild increases in the serum calcium concentration, and hypercalcemia is discovered only after a serum biochemistry panel is performed, often for unrelated reasons. When clinical signs do develop, they initially tend to be insidious in onset. The severity of clinical signs depends in part on the severity, rate of onset, and duration of the hypercalcemia. Clinical signs become more severe as the magnitude of the hypercalcemia increases, regardless of the rate of onset or duration. Clinical signs are usually mild with serum calcium concentrations less than 14 mg/dl, are readily apparent with concentrations greater than 14 mg/dl, and become potentially life-threatening (i.e., cardiac arrhythmias) when the serum calcium concentration exceeds 18 to 20 mg/dl. Clinical signs resulting from the development of calcium uroliths may also occur.

#### **Diagnosis**

Hypercalcemia should always be reconfirmed, preferably from a nonlipemic blood sample obtained from the dog or cat following a 12-hour fast, before embarking on an extensive diagnostic evaluation. Results of a CBC, serum biochemistry panel, and urinalysis, in conjunction with the history and physical examination findings, often provide clues to the diagnosis (see Table 50-2). Special attention should be paid to the serum electrolytes and renal parameters. Hypoadrenocorticism-induced hypercalcemia typically occurs in conjunction with mineralocorticoid deficiency; hyponatremia, hyperkalemia, and prerenal azotemia should be present. The serum phosphorus concentration is in the lower half of the normal range or low with HHM and primary hyperparathyroidism (Fig. 55-2). If the serum phosphorus concentration is increased and renal function is normal, hypervitaminosis D and bone osteolysis from metastatic or primary bone neoplasia are the primary differentials.

Determining whether renal failure is primary or secondary to hypercalcemia caused by another disorder when hyperphosphatemia and hypercalcemia co-exist with azotemia can be difficult. Chronic and, less commonly, acute renal failure can cause hypercalcemia. Alternatively, disorders that cause persistent hypercalcemia with a concurrent high-

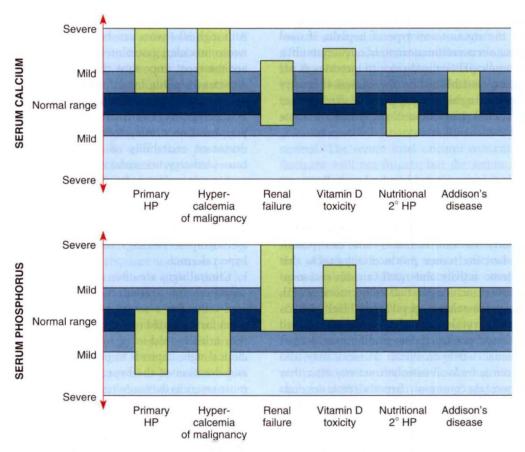

FIG 55-2
The range in serum calcium and phosphorus concentrations for the more common causes of hypercalcemia and/or hyperparathyroidism in the dog. HP, Hyperparathyroidism; 2° HP, secondary hyperparathyroidism. (From Feldman EC, Nelson RW: Canine and feline endocrinology and reproduction, ed 3, Philadelphia, 2004, WB Saunders.)

normal to increased serum phosphorus concentration can cause progressive mineralization of the kidney and eventual renal failure. Measurement of the serum ionized calcium concentration may help identify dogs and cats with renal failure—induced hypercalcemia; serum ionized calcium concentrations are typically normal or decreased in renal failure and increased in hypercalcemia caused by other disorders.

Hypercalcemia of malignancy and primary hyperparathyroidism are the primary differentials when hypercalcemia and normal-to-low serum phosphorus concentrations are identified. The most common malignancy is lymphoma. A careful review of the history and physical examination findings may provide clues to the diagnosis. Systemic signs of illness suggest hypercalcemia of malignancy. Dogs and cats with primary hyperparathyroidism are usually healthy, and clinical signs are mild. The appendicular skeleton, peripheral lymph nodes, abdominal cavity, and rectum should be carefully palpated for masses, lymphadenopathy, hepatomegaly, splenomegaly, or pain on digital palpation of the long bones. Diagnostic tests that are helpful in identifying the underlying malignancy include thoracic and abdominal radiographs; abdominal ultrasound; cytologic evaluation of aspirates of the liver, spleen, lymph nodes, and bone marrow; determination of the serum ionized calcium, PTH, and PTHrP concentrations; and cervical ultrasound.

Sternal and hilar lymphadenopathy is common with lymphoma-induced hypercalcemia and can be readily identified with thoracic radiographs. Radiographs of the thorax and abdomen can also be used to evaluate bones; discrete lytic lesions in the vertebrae or long bones suggest multiple myeloma. Hyperproteinemia, proteinuria, and plasma cell infiltration in the bone marrow suggest multiple myeloma. Cytologic evaluation of peripheral lymph node, bone marrow, and splenic aspirates can be helpful in identifying lymphoma; involvement of the peripheral lymph nodes or spleen by lymphoma can be present without causing their enlargement. Ideally, the largest lymph node should be evaluated. Normal lymph node, bone marrow, and splenic aspirates do not rule out lymphoma.

Measurement of the serum ionized calcium, PTH, and PTHrP levels from the same blood sample is helpful in differentiating primary hyperparathyroidism from HHM. Excessive secretion of biologically active PTHrP plays a central role in the pathogenesis of hypercalcemia in most forms of HHM. An increased serum ionized calcium concentration, a detectable serum PTHrP concentration, and a

nondetectable serum PTH concentration are diagnostic for HHM. Lymphoma is the most common cause of detectable PTHrP concentrations, but other tumors, including apocrine gland adenocarcinoma and various carcinomas (e.g., mammary gland, squamous cell, bronchogenic), can also cause hypercalcemia by this mechanism. In contrast, an increased serum ionized calcium concentration, a normal to increased serum PTH concentration, and a nondetectable PTHrP concentration are diagnostic of primary hyperparathyroidism. Ultrasonographic examination of the thyroparathyroid complex may reveal enlargement of one or more parathyroid glands. Most parathyroid adenomas measure 4 to 10 mm in greatest diameter, although parathyroid adenomas can exceed 2 cm. In contrast, the parathyroid glands will be small or undetectable with hypercalcemia of malignancy.

Evaluation of the change in the serum calcium concentration following L-asparaginase administration should be considered for the animal with hypercalcemia of undetermined etiology to rule out occult lymphoma. For the l-asparaginase trial 20,000 IU/m² of the drug is administered intravenously, and the serum calcium concentration is measured before and every 12 hours after administration for as long as 72 hours. A decline in the serum calcium level, usually into the normal range, is strongly suggestive of occult lymphoma. Hypersensitivity reactions are the most common adverse effect associated with l-asparaginase administration; pretreatment with an antihistamine is recommended.

Idiopathic hypercalcemia is a common diagnosis in young and middle-aged cats that is established by ruling out the other causes of hypercalcemia. Hypercalcemia is usually mild (less than 13 mg/dl), and cats are usually asymptomatic. The serum phosphorus concentration and renal parameters are normal. The etiology is unknown. The results of a complete diagnostic evaluation, as described previously, are unremarkable. Serum PTH concentrations are in the normal range or low; primary hyperparathyroidism has not been confirmed in any of these cats. Excessive serum PTHrP, 25hydroxyvitamin D or calcitriol concentrations have not been identified. Nephrocalcinosis and urolithiasis may develop, presumably secondary to increased urinary calcium excretion. Effective treatment has not been identified primarily because the pathogenesis of this problem remains unknown. Serum calcium concentrations have decreased in some cats after a change to a high-fiber diet or renal diets containing low calcium and phosphorus content or after prednisone treatment (initial dose, 5 mg q24h) was initiated, but the response has been unpredictable and often short-lived. Preliminary trials with oral biphosphonates (e.g., alendronate) have been promising in some cats with idiopathic hypercalcemia (see treatment section). Serum calcium, phosphorus, and renal parameters should be monitored periodically in affected cats and appropriate therapy initiated if renal insufficiency begins to develop (see Chapter 44).

#### **Treatment**

Medical therapy should be directed at eradicating the underlying cause of the hypercalcemia. Supportive therapy to

#### Nonspecific Therapy for Control of Hypercalcemia

#### **Acute Therapy**

- 1. Correct fluid deficits
- 2. Physiologic saline diuresis, 60-180 mg/kg/day IV
- 3. Furosemide, 2-4 mg/kg IV, IM, PO q8-12h
- Once diagnosis has been established: prednisone, 1-2 mg/kg q12h

#### Additional Therapy If Above Fails

- 1. Sodium bicarbonate, 1-4 mEq/kg given by slow bolus
- 2. Calcitonin, 4-8 IU/kg SC q8-12h
- 3. Bisphosphonates (pamidronate, 1-2 mg/kg IV)
- 4. Peritoneal dialysis, hemodialysis

#### Long-Term Therapy

- 1. Furosemide (see above)
- 2. Prednisone (see above)
- 3. Low-calcium diet (e.g., Prescription Diet k/d, u/d, s/d)
- Intestinal phosphate binders if hyperphosphatemia present (see Chapter 44)
- 5. Bisphosphonates (pamidronate (see above); etidronate, 10-40 mg/kg PO divided q8-12h)

IV, Intravenous; IM, intramuscular; PO, by mouth; SC, subcutaneous.

decrease the serum calcium concentration to less toxic levels is indicated if clinical signs are severe, if the serum calcium concentration is greater than 16 mg/dl, if the calcium-phosphorus solubility product ([Ca]  $\times$  [Pi]) is greater than 60 to 70 (implying metastatic mineralization of soft tissues), or if azotemia is present. In dogs and cats correction of fluid deficits, saline diuresis, diuretic therapy with furosemide, and corticosteroids are the most commonly used modes of therapy (Box 55-6). Prerenal azotemia is common in dogs with hypercalcemia secondary to water restriction imposed by owners concerned about the polyuria and polydipsia. As such, diuretics should never be administered before volume replenishment is completed.

The supportive therapy implemented should not interfere with attempts to establish a definitive diagnosis. As a general rule, saline diuresis followed by diuretic therapy can be initiated without compromising the results of diagnostic tests. Because of the high incidence of lymphoma in animals with hypercalcemia, glucocorticoids should not be administered unless the cause of the hypercalcemia has been identified.

Calcitonin may be useful in the treatment of animals with severe hypercalcemia and could be used in lieu of prednisone for treating hypercalcemia in animals without a definitive diagnosis. Calcitonin inhibits osteoclast activity. It has been used most commonly to treat hypercalcemia in dogs with cholecalciferol rodenticide toxicosis. The decrease in the serum total calcium concentration after calcitonin administration is relatively small (3 mg/dl or less), and adverse reactions include anorexia and vomiting. Although the onset of

action of calcitonin may be rapid, its effect may be short-lived (hours), and resistance often develops within a few days, presumably because of downregulation of calcitonin receptors. The transitory effect of calcitonin and its expense have limited its usefulness for treating hypercalcemia.

Bisphosphonates inhibit bone resorption by decreasing osteoclast activity and function and inducing osteoclast apoptosis and are used for maintenance treatment of hypercalcemia of malignancy, osteoporosis, and malignancyinduced bone pain in humans. Pamidronate (Aredia, Novartis) has been used to treat dogs and cats with a variety of disorders causing hypercalcemia, including cholecalciferol rodenticide toxicosis, hypercalcemia caused by lymphoma, myeloma, primary hyperparathyroidism, and nocardiosis. The IV administration of pamidronate has a rapid onset of action and is effective in lowering serum total and ionized calcium concentrations. The only adverse reaction reported with pamidronate is renal toxicity, which appears to be uncommon. Factors that affect onset of renal toxicity in humans include type of bisphosphonate administered, rate of infusion, and hydration status of the patient. Administration of pamidronate before a definitive diagnosis has been obtained should not adversely affect establishing the cause of the hypercalcemia. Unfortunately, expense limits the usefulness of pamidronate for treating hypercalcemia in animals. The reader is referred to Suggested Readings for more information on bisphosphonates.

The duration of therapy for hypercalcemia depends on the reversibility of the underlying cause. If prolonged supportive therapy is required (e.g., in an animal with cholecal-ciferol rodenticide toxicity or nontreatable malignancy), furosemide, corticosteroids, and a low-calcium diet (e.g., Prescription Diets u/d and s/d canned, Hill's Pet Products) can be used to help control the hypercalcemia. Noncalcium-containing intestinal phosphorus binders (e.g., aluminum hydroxide) should be administered if hyperphosphatemia is present. Oral or IV administration of bisphosphonates, as needed to control hypercalcemia, may also be considered (see Suggested Readings).

#### HYPOCALCEMIA

#### Etiology

Hypocalcemia is present if the serum total calcium concentration is less than 9 mg/dl in adult dogs and less than 8 mg/dl in adult cats or if the serum ionized calcium concentration is less than 1.0 mmol/L, although reference ranges may vary between laboratories. Hypocalcemia develops after increased calcium loss in milk (e.g., puerperal tetany), decreased calcium resorption from bone or kidney (e.g., primary hypoparathyroidism), decreased calcium absorption from the gastrointestinal tract (e.g., malassimilation syndromes), or increased precipitation-chelation of serum calcium (e.g., ethylene glycol toxicity, acute pancreatitis). The acute onset of hyperphosphatemia can also cause hypocalcemia. The most common causes of hypocalcemia in dogs and cats are

puerperal tetany, acute and chronic renal failure, malassimilation syndromes, and primary hypoparathyroidism (especially after thyroidectomy in hyperthyroid cats; see Table 50-3). The serum total calcium concentration is typically decreased in animals with concurrent hypoalbuminemia for reasons discussed in the section on hypercalcemia. Depending on the underlying etiology, the serum ionized calcium concentration may or may not be decreased. Measurement of serum ionized calcium should be done before rendering a diagnosis of hypocalcemia in an animal with decreased serum total calcium and albumin concentrations.

#### **Clinical Features**

Animals with hypocalcemia range from being asymptomatic to showing severe neuromuscular dysfunction. Serum total calcium concentrations between 7.5 and 9 mg/dl are often clinically silent; clinical signs usually occur if values are less than 7 mg/dl. The presence and severity of signs depend on the magnitude, rapidity of onset, and duration of hypocalcemia.

The most common clinical signs are directly attributable to a hypocalcemia-induced increase in neuronal excitability and include nervousness, behavioral changes, focal muscle twitching (especially ear and facial muscles), muscle cramping, stiff gait, tetany, and seizures. The seizures are not usually associated with loss of consciousness or urinary incontinence. Early indicators of hypocalcemia, especially in cats, include lethargy, anorexia, intense facial rubbing, and panting. Exercise, excitement, and stress may induce or worsen clinical signs. Additional physical examination findings may include fever, a "splinted" abdomen, cardiac abnormalities (e.g., weak femoral pulses, muffled heart sounds, tachyarrhythmias), and cataracts.

#### Diagnosis

Hypocalcemia should be confirmed before initiating diagnostic tests to identify the cause. The list of differential diagnoses for hypocalcemia is relatively short, and the history, physical examination findings, CBC, serum biochemistry panel, urinalysis, and tests for pancreatitis (e.g., pancreatic lipase immunoreactivity, abdominal ultrasound) usually provide the clues necessary to establish the diagnosis (see Table 50-3). Primary hypoparathyroidism is the most likely diagnosis in the nonazotemic, nonlactating dog or cat with clinical signs of hypocalcemia. The finding of a low or non-detectable baseline serum PTH concentration confirms this diagnosis.

#### **Treatment**

Therapy should be directed at eradicating the underlying cause of the hypocalcemia. Vitamin D, calcium, or both are indicated if clinical signs of hypocalcemia are present, if the serum calcium concentration is less than 7.5 mg/dl, or if the serum ionized calcium concentration is less than 0.8 mmol/L. If hypocalcemic tetany is present, calcium should be administered intravenously slowly to effect (Box 55-7). Calcium gluconate is the preferred agent because it is not

# Treatment Of Hypocalcemia in Dogs and Cats

#### **Immediate Treatment of Symptomatic Hypocalcemia**

Calcium gluconate (preferred) or calcium chloride 10% solution

Dosage: 0.5-1.5 ml/kg IV slowly to effect Monitor for bradycardia and arrythmias Goal: Resolve clinical signs of hypocalcemia

### Parenteral Treatment to Prevent Symptomatic Hypocalcemia

Continuous IV infusion of 10% calcium gluconate (preferred)

Initial dosage: 60 to 90 mg elemental calcium/kg/day 10 ml of 10% calcium gluconate provides 93 mg of elemental calcium

Administer via syringe pump in separate IV line

Do not add to fluids containing lactate, acetate, bicarbonate or phosphates

Monitor serum ionized or total calcium q8-12h, and adjust infusion rate accordingly

Goal: to avoid clinical signs of hypocalcemia while correcting etiology and/or waiting for oral calcium and vitamin D therapy to take effect

Periodic SC administration of calcium gluconate

Dilute 10% calcium gluconate at least 1:2 with physiologic saline before administration

Do not administer calcium chloride subcutaneously; sloughing of skin may occur

Dosage based on amount of IV calcium required to control clinical signs during treatment of symptomatic hypocalcemia (see above)

Administer q6-8h

Monitor serum ionized or total calcium prior to injection and adjust dosage or frequency of administration accordingly

Goal: to avoid clinical signs of hypocalcemia while correcting etiology and/or waiting for oral calcium and vitamin D therapy to take effect

#### Oral Vitamin D and Calcium Treatment for Hypocalcemia

1,25-dihydroxy vitamin  $D_3$  (calcitriol) is preferred because of its fast onset of action

Available as 0.25-µg capsules

Initial dosage: 0.02-0.03 µg/kg/day (compounding of drug often required)

Monitor serum ionized or total calcium q12-24h, and adjust dosage or frequency of administration accordingly

Goal: to avoid clinical signs of hypocalemia and development of hypercalcemia; target total calcium concentration is between 9 and 10 mg/dl

Dihydrotachysterol (Hytakerol) has a slower onset of action compared with calcitriol

Available as 0.125-mg tablets and capsules and 0.25 mg/ml oral solution

Initial dosage: 0.02-0.03 mg/kg/day

Monitor serum ionized or total calcium q12-24h and adjust dosage or frequency of administration accordingly

Goal: to avoid clinical signs of hypocalemia and development of hypercalcemia; target total calcium concentration is between 9 and 10 mg/dl

Oral calcium gluconate, calcium lactate, or calcium carbonate tablets

Various tablet strengths available, ranging from 30 to 500 mg of calcium/tablet

Initial dosage: approximately 25 mg of Ca/kg q8-12h

Typically used in conjunction with vitamin D

Dosage and frequency of administration adjusted on the basis of serum ionized or total calcium concentrations

IV, Intravenous; SC, subcutaneous.

caustic if administered outside of the vein, unlike calcium chloride. Auscultation and electrocardiographic monitoring is advisable during calcium administration; if bradycardia or shortening of the QT interval occurs, the IV infusion should be stopped briefly. Calcium-rich fluids should be infused with caution in dogs or cats with hyperphosphatemia because they can increase the probability of metastatic calcification of soft tissues, most notably in the kidney.

Once signs of hypocalcemic tetany have been controlled with IV calcium, oral vitamin D, oral or injectable calcium (or both) may be needed to prevent the recurrence of clinical signs. If the cause of hypocalcemia is readily reversible and the hypocalcemia is anticipated to be short-lived (e.g., weaning puppies from bitch with puerperal tetany), an injection of calcium gluconate subcutaneously may be all that is necessary to prevent the recurrence of clinical signs. The clinician can determine the dose of IV calcium gluconate required to control tetany originally, and this dose can then

be administered subcutaneously after the calcium gluconate has been diluted at least 1:2 by volume with saline. Calcium chloride should never be administered subcutaneously because it is highly irritating to tissues and may cause sluffing of the skin.

In animals with disorders causing prolonged hypocalcemia (e.g., primary hypoparathyroidism), calcium gluconate should be administered by continuous IV infusion at an initial dosage of 60 to 90 mg of elemental calcium/kg/day. Ten milliliters of 10% calcium gluconate provides 93 mg of elemental calcium. Approximately 1, 2, and 3 mg/kg/hour elemental calcium is provided when 10, 20, or 30 ml of 10% calcium gluconate, respectively, is added to 250 ml of fluids and administered at a maintenance rate of 60 ml/kg/day (2.5 ml/kg/hour). Calcium salts should not be added to fluids that contain lactate, acetate, bicarbonate, or phosphates because calcium salt precipitates can result. The serum calcium concentration should be measured daily and

calcium therapy gradually decreased and then discontinued once the serum total calcium concentration is consistently greater than 8 mg/dl or the serum ionized calcium concentration is greater than 0.9 mmol/L.

Long-term maintenance therapy may be necessary to control hypocalcemia. It is most commonly required for the control of primary hypoparathyroidism and hypoparathyroidism occurring after bilateral thyroidectomy in cats with hyperthyroidism. Oral vitamin D administration is the primary mode of treatment for the management of chronic hypocalcemia (see Box 55-7). Vitamin D works by stimulating intestinal calcium and phosphorus absorption and, together with parathyroid hormone, by mobilizing calcium and phosphorus from bone. Oral calcium supplements are needed early in maintenance therapy in addition to vitamin D.

The aim of maintenance therapy is to keep the serum calcium concentration between 9 and 10 mg/dl, which controls clinical signs, lessens the risk of hypercalcemia, and provides some stimulus for remaining or ectopic parathyroid tissue to become functional. The serum calcium concentration should be monitored closely (initially q24-48h) and adjustments in therapy made accordingly. Vitamin D therapy is required permanently in animals with primary hypoparathyroidism and in animals that have undergone total parathyroidectomy. Vitamin D therapy can usually be tapered and discontinued if there is only partial or transient parathyroid damage. Regardless, calcium supplementation often may be tapered and stopped. See Chapter 50 for more information on the treatment of hypocalcemia.

# **HYPERPHOSPHATEMIA**

#### Etiology

Hyperphosphatemia is present when the serum phosphorus concentration is greater than 6.5 mg/dl in the adult dog and cat, although reference ranges may vary between laboratories. Serum phosphorus concentrations are highest (often greater than 6.5 mg/dl) in dogs and cats younger than 6 months of age and gradually decrease to adult values after 1 year of age. Bone growth and an increase in renal tubular reabsorption of phosphorus mediated by growth hormone are believed to contribute to this age effect. Hyperphosphatemia can result from increased intestinal phosphorus absorption, decreased phosphorus excretion in the urine, or a shift in phosphorus from the intracellular to the extracellular compartment. Translocation of phosphorus between the intracellular and extracellular compartment is similar to that of potassium. The most common cause of hyperphosphatemia in dogs and cats is decreased renal excretion secondary to renal failure (Box 55-8).

### **Clinical Features**

Hyperphosphatemia is a marker of underlying disease. By itself, hyperphosphatemia usually does not cause clinical signs. An acute increase in serum phosphorus may cause

hypocalcemia and its associated neuromuscular signs. Sustained hyperphosphatemia can cause secondary hyperparathyroidism, fibrous osteodystrophy, and metastatic calcification in extraosseous sites. Fortunately, most causes of hyperphosphatemia cause a decrease in serum calcium concentration so that the calcium-phosphorus solubility product ([Ca]  $\times$  [Pi]) remains less than 60. The risk of soft tissue mineralization increases when the [Ca]  $\times$  [Pi] solubility product exceeds 60 to 70. Chronic renal failure is the most common cause of sustained hyperphosphatemia and an increase in the solubility product above 60 to 70.

#### **Treatment**

Hyperphosphatemia usually resolves with correction of the underlying disease. In dogs and cats with renal failure, hyperphosphatemia can initially be lowered with aggressive fluid therapy. Low-phosphorus diets and orally administered phosphate binders are the most effective way to treat sustained hyperphosphatemia caused by renal failure (see Chapter 44).

### **HYPOPHOSPHATEMIA**

# **Etiology**

Hypophosphatemia is present when the serum phosphorus concentration is less than 3 mg/dl in the dog and cat, although reference ranges may vary between laboratories. Hypophosphatemia is usually not clinically worrisome until the serum phosphorus concentration is less than 1.5 mg/dl. Hypophosphatemia results from decreased phosphorus absorption in the intestinal tract, increased urinary phosphorus excretion, or translocation from the extracellular to the intracellular compartment. The most common cause of clinically significant hypophosphatemia in the dog and cat occurs within the first 24 hours of therapy for diabetic ketoacidosis, when there is a shift of potassium and phosphorus from the extracellular to the intracellular compartment (Box 55-9). Translocation of phosphorus between the intracellular and

DKA, Diabetic ketoacidosis.

extracellular compartments is similar to that seen with potassium. Factors that promote a shift of potassium into the intracellular compartment (e.g., alkalosis, insulin, glucose infusion) promote a similar shift in phosphorus. During therapy for diabetic ketoacidosis the serum phosphorus concentration can decline to severe levels (i.e., less than 1 mg/dl) as a result of the dilutional effects of fluid therapy and the intracellular shift of phosphorus after the initiation of insulin and bicarbonate therapy. Interestingly, the initial serum phosphorus concentration is usually normal or only mildly decreased because the metabolic acidosis of diabetic ketoacidosis results in a shift of phosphorus from the intracellular to the extracellular compartment.

#### **Clinical Features**

Clinical signs may develop when the serum phosphorus concentration is less than 1.5 mg/dl, although signs are quite variable, and severe hypophosphatemia is clinically silent in many animals. Hypophosphatemia primarily affects the hematologic and neuromuscular systems in the dog and cat. Hemolytic anemia is the most common sequela to hypophosphatemia. Hypophosphatemia decreases the erythrocyte concentration of ATP, which increases erythrocyte fragility, leading to hemolysis. Hemolysis is usually not identified until the serum phosphorus concentration is 1 mg/dl or less. Hemolytic anemia can be life-threatening if not recognized and treated. Neuromuscular signs include weakness, ataxia, and seizures, as well as anorexia and vomiting secondary to intestinal ileus.

# **Treatment**

For most dogs and cats hypophosphatemia resolves after correction of the underlying cause. Phosphate therapy is probably not indicated for asymptomatic animals in which the serum phosphorus concentration is greater than 1.5 mg/dl and is unlikely to decrease further. Phosphate therapy is indicated if clinical signs or hemolysis are identified or if the serum phosphorus concentration is less than 1.5 mg/dl, especially if a further decrease is possible. Phosphate supplementation is not indicated in dogs and cats with hypercalcemia, hyperphosphatemia, oliguria, or suspected tissue necrosis. If renal function is in question, phosphorus supplementation should not be done until the status of renal function and serum phosphorus concentration are known.

The goal of therapy is to maintain the serum phosphorus concentration greater than 2 mg/dl without causing hyperphosphatemia. Oral phosphate supplementation is preferred, using a buffered laxative (e.g., Phospho-Soda, Fleet Pharmaceuticals), balanced commercial diets, milk, or a combination of these. IV phosphate supplementation is usually required to correct severe hypophosphatemia, especially in animals with diabetic ketoacidosis. Potassium phosphate solutions are typically used. If potassium supplementation is contraindicated, sodium phosphate solutions can be substituted. Potassium and sodium phosphate solutions contain 3 mmol of phosphate per milliliter and either 4.4 mEq of potassium or 4 mEq of sodium per milliliter. The initial

<sup>\*</sup>Common causes.

dosage of phosphate is 0.01 to 0.03 mmol/kg/hour, preferably administered by constant rate infusion in calcium-free IV fluids (i.e., 0.9% sodium chloride). In dogs and cats with severe hypophosphatemia, it may be necessary to increase the dosage to 0.03 to 0.12 mmol/kg/hour. Because the dose of phosphate necessary to replete an animal and the animal's response to therapy cannot be predicted, it is important to initially monitor the serum phosphorus concentration every 8 to 12 hours and adjust the phosphate infusion accordingly. Adverse effects from overzealous phosphate administration include iatrogenic hypocalcemia and its associated neuromuscular signs, hypernatremia, hypotension, and metastatic calcification. Serum total or preferably ionized calcium concentration should be measured at the same time as serum phosphorus concentration and the rate of phosphate infusion decreased if hypocalcemia is identified.

# HYPOMAGNESEMIA

# Etiology

Hypomagnesemia is present if the serum total and ionized magnesium concentration are less than 1.5 mg/dl and 1.0 mg/dl, respectively, although reference ranges may vary between laboratories. Hypomagnesemia results from decreased oral intake or gastrointestinal tract absorption of magnesium (e.g., small intestinal disease causing malabsorption), increased gastrointestinal tract loss (e.g., protracted vomiting, diarrhea), increased urinary magnesium excretion (e.g., interstitial nephritis, diuretics), or translocation of the cation from the extracellular to the intracellular compartment. The most common causes of clinically significant hypomagnesemia in dogs and cats include disorders causing small intestinal malassimilation; renal disorders associated with a high urine output; the osmotic diuresis of diabetic ketoacidosis; and the shift of potassium, phosphorus, and magnesium from the extracellular to the intracellular compartment that occurs within the first 24 hours of therapy for diabetic ketoacidosis (Box 55-10). Magnesium is predominantly an intracellular cation. The nature of the translocation of magnesium between the intracellular and the extracellular compartments is similar to that of potassium in that factors that promote a shift of potassium into the intracellular compartment (e.g., alkalosis, insulin, glucose infusion) promote a similar shift in magnesium.

# **Clinical Features**

Hypomagnesemia is reported to be the most common electrolyte disorder in critically ill dogs and cats, and magnesium deficiency may predispose animals to a variety of cardiovascular, neuromuscular, and metabolic complications. Clinical signs of hypomagnesemia do not usually occur until the serum total and ionized magnesium concentrations are less than 1.0 mg/dl and 0.5 mg/dl, respectively, and even at these low levels, many animals remain asymptomatic. A magnesium deficiency can result in several nonspecific clinical signs, including lethargy, anorexia, muscle weakness (includ-

\*Common causes.

ing dysphagia and dyspnea), muscle fasciculations, seizures, ataxia, and coma. Concurrent hypokalemia, hyponatremia, and hypocalcemia occur in animals with hypomagnesemia, although the prevalence of these electrolyte abnormalities may differ between species. These electrolyte abnormalities may also contribute to the development of clinical signs. Magnesium is a cofactor for all enzyme reactions that involve ATP, most notably the sodium-potassium ATPase pump. Deficiencies in magnesium can lead to potassium wastage from the body, and the resultant hypokalemia may be refractory to appropriate potassium replacement therapy.

Magnesium deficiency inhibits PTH secretion from the parathyroid gland, resulting in hypocalcemia. Magnesium deficiency causes the resting membrane potential of myocardial cells to be decreased and leads to increased Purkinje fiber excitability, with the consequent generation of arrhythmias. Electrocardiographic changes include a prolonged PR interval, widened QRS complex, depressed ST segment, and peaked T waves. Cardiac arrhythmias associated with magnesium deficiency include atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation. Hypomagnesemia also predisposes animals to digitalis-induced arrhythmias.

# Diagnosis

Measurement of serum total and ionized magnesium is indicated in those dogs and cats with disorders and predisposing factors that are associated with hypomagnesemia (see Box 55-10). Assessing an animal's magnesium status is problematic, however, because there is no simple, rapid, and accurate laboratory test to gauge total body magnesium status. Serum total magnesium represents 1% of the body's magnesium stores, and serum ionized magnesium represents 0.2% to 0.3% of total body magnesium stores. As a result, serum total and ionized magnesium concentrations do not always reflect total body magnesium status. A normal serum magnesium concentration may exist despite an intracellular magnesium deficiency. However, a low serum magnesium concentration would support the presence of a total body magnesium deficiency, especially when clinical signs or concurrent electrolyte abnormalities are consistent with hypomagnesemia.

#### **Treatment**

To date there are no clinical studies that have yielded guidelines for magnesium replacement in dogs and cats; currently, it is determined empirically. Hypomagnesemia is not generally a concern for dogs and cats eating commercial diets. Treatment of hypomagnesemia usually involves sick dogs and cats that are hospitalized and have problems with inappetence and/or excessive fluid loss from the gastrointestinal tract or kidneys. Treatment of hypomagnesemia may also be indicated during treatment of diabetic ketoacidosis in dogs and cats with refractory hypokalemia, hypocalcemia, or both and in dogs or cats in heart failure with concurrent ventricular arrhythmias that are being treated with loop diuretics, digitalis, or both.

Parenteral solutions of magnesium sulfate (8.12 mEq of magnesium per gram of salt) and magnesium chloride (9.25 mEq of magnesium per gram of salt) are available commercially. The IV dose for rapid and slow magnesium replacement is 0.75 to 1 mEq/kg/day and 0.3 to 0.5 mEq/kg/day, respectively, administered by constant-rate infusion in 5% dextrose in water. Magnesium is incompatible with solutions containing bicarbonate or calcium. Renal function should be assessed before the administration of magnesium and the magnesium dose reduced by 50% to 75% in azotemic animals. The use of magnesium with digitalis cardio-

glycosides may cause serious conduction disturbances. Serum magnesium, calcium, and potassium concentrations should be monitored daily. The goal of magnesium therapy is the resolution of clinical signs or refractory hypokalemia and hypocalcemia. The parenteral administration of magnesium sulfate may cause significant hypocalcemia such that calcium infusion may be necessary. Other adverse effects of magnesium therapy include hypotension; atrioventricular and bundle-branch blocks; and, in the event of overdose, respiratory depression and cardiac arrest. Overdoses are treated with IV calcium gluconate (see Box 55-7).

# HYPERMAGNESEMIA

# Etiology

Hypermagnesemia is present if the serum total and ionized magnesium concentration is greater than 2.5 mg/dl and 1.5 mg/dl, respectively, although reference ranges may vary between laboratories. It is an uncommon clinical problem, owing to the remarkable ability of the kidney to efficiently eliminate excessive magnesium. Hypermagnesemia may occur in dogs and cats with renal failure and postrenal azotemia and iatrogenically after an excessive intake of magnesium (e.g., IV administration). Because excess magnesium is rapidly excreted by the healthy kidney, iatrogenic hypermagnesemia usually occurs in animals with renal insufficiency. Hypermagnesemia has also been reported in cats with thoracic neoplasia and pleural effusion, although the mechanism involved with the development of hypermagnesemia in these cats is unknown.

# **Clinical Features**

Clinical manifestations of hypermagnesemia include lethargy, weakness, and hypotension. Loss of deep tendon reflexes and electrocardiographic changes, consisting of prolonged PR intervals, widening QRS complexes, and heart block, occur at higher serum magnesium concentrations. Serious complications, including respiratory depression, apnea, cardiac arrhythmias, and cardiac arrest, occur when serum magnesium concentrations exceed 12 mg/dl. At these high levels magnesium acts as a nonspecific calcium-channel blocker.

# **Diagnosis**

Measurement of the serum magnesium concentration identifies hypermagnesemia. Unlike magnesium depletion, serum concentrations cannot be normal if there is an increase in magnesium stores (see the section on hypomagnesemia). A correlation between increased serum magnesium concentrations and the severity of total body excess has not been reported.

### **Treatment**

Treatment begins with the discontinuation of all exogenous sources of magnesium. Additional treatment depends on the severity of the hypermagnesemia, the clinical presentation, and the status of renal function. Most dogs and cats with healthy kidneys require only supportive care and observation. Treatment aimed at improving renal function is indicated in animals with concurrent renal insufficiency (see Chapter 44). Saline diuresis and administration of loop diuretics (e.g., furosemide) will accelerate renal magnesium excretion. Administration of IV calcium is indicated in dogs and cats with cardiac arrhythmias or significant hypotension (see Box 55-7).

# NORMAL ESTROUS CYCLE

# THE BITCH

The average age at the time of puberty in bitches is 9 to 10 months, and the range is 6 to 24 months of age. The interval from the beginning of one cycle to the beginning of the next, or the interestrous interval, varies from 4 to 12 months and averages 7 months. Therefore bitches have only one or two cycles per year. The interestrous interval is extremely variable within individual bitches, more so than it is among bitches. Because of this variability, the past interestrous interval does not accurately predict the next cycle in an individual bitch. Although a few bitches are very consistent, in most there is more than a month's variation from cycle to cycle. The interestrous interval is not influenced by pregnancy or the photoperiod, although breeds such as the Basenji cycle only once each year, indicating a possible effect of the photoperiod in some individuals.

The estrous cycle in the bitch is divided into four components: proestrus, estrus, diestrus, and anestrus. Proestrus and estrus together are often referred to as *heat* or *season*. Together they constitute the follicular phase of the reproductive cycle. The luteal phase of the cycle is referred to as *diestrus*. The canine estrous cycle is distinctly different from that of other domestic species in several regards. These include the very long anestrus (months as opposed to days or weeks), the long proestrus and estrus (days to weeks as opposed to hours or days), the fact that the corpora luteal lifespan is independent of the presence (or absence) of pregnancy, ovulation of an immature oocyte, and long viability (days as opposed to hours) of oocyte and sperm within the female tract.

#### **Proestrus**

Proestrus is considered to begin when vulvar swelling and a sanguineous discharge are first observed. It ends when the bitch allows copulation. The average duration of proestrus is 9 days, and the range is 3 to 17 days. Attractiveness and

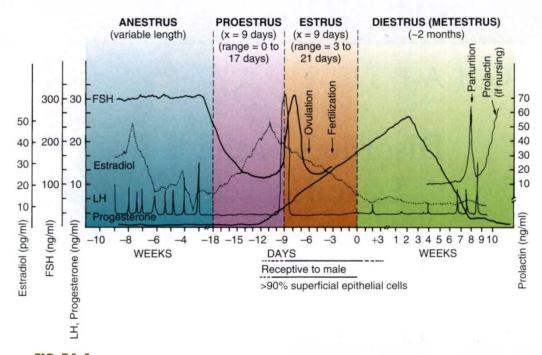

FIG 56-1 The canine estrous cycle. (From Morrow DA, editor: Current therapy in theriogenology, ed 2, Philadelphia, 1986, WB Saunders.)

receptivity to male dogs gradually increase throughout proestrus. The factors that end anestrus and initiate a new follicular phase in the bitch are poorly understood. Throughout anestrus follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are secreted concomitantly, in a pulsatile pattern. The FSH pulses are of lesser magnitude but longer duration than are the LH pulses. Basal concentrations of FSH increase as anestrus progresses, whereas basal LH concentrations are unchanged. The increase in FSH concentrations is considered crucial to initiate ovarian follicular development and the onset of proestrus. The developing ovarian follicles are 1.5 to 5 mm in diameter. They produce estrogens, the most important of which is estradiol 17-1. Estradiol causes the vulvar swelling, vaginal edema and cornification, and uterine bleeding that is recognized by a serosanguineous vulvar discharge. Estradiol serum concentrations gradually increase during early proestrus. They increase sharply just before the preovulatory LH surge and rapidly decline to basal levels thereafter (Fig. 56-1).

Under the influence of estrogen the vaginal epithelial cells proliferate and mature (cornification). The stratified squamous epithelium increases in thickness from a few cell layers in anestrus to 20 to 30 cell layers in late proestrus. The degree of estrogenic influence and therefore the stage of the estrous cycle with respect to the serum estrogen concentration can be monitored by vaginal cytology (see p. 891).

#### Estrus

Behavioral estrus is characterized by acceptance of mating. The bitch's feet are firmly planted to allow the male to mount—hence the term standing heat (Fig. 56-2). The tail is

deviated to the side to allow intromission; this behavior has been referred to as flagging. Stroking the perineum may occasionally elicit flagging, which would be an indication that the bitch is in estrus. The average duration of estrus is 9 days, and the range is 3 to 21 days. The swollen vulva is less turgid than during proestrus. The vulvar discharge of estrus is usually less bloody than that of proestrus, but normal bitches often have a sanguineous discharge throughout both. Therefore changes in the gross appearance of the discharge are not necessarily indicators of the transition from proestrus to estrus.

The preovulatory follicles have reached 3 to 8 mm in diameter. The increase in estradiol concentrations during proestrus, via positive feedback to the hypothalamus, initiates the LH surge, which in turn causes ovulation and the subsequent formation of corpora lutea (CL) and progesterone secretion by the ovary (Fig. 56-1). In the bitch the initial increase in progesterone secretion coincides with the LH surge. Although the onset of behavioral estrus usually occurs within a day or two of the LH surge, behavioral estrus may occur as early as 4 days before or as late as 6 days after the LH surge. Therefore the day on which a bitch allows copulation is not closely associated with the LH surge or ovulation.

In most bitches ovulation occurs within 48 hours of the LH surge (the range is 0 to 96 hours). Ovulation from both ovaries is apparently completed within 24 hours. Primary oocytes (prophase I) are ovulated and resume meiosis during tubal transport. By 2 to 3 days after ovulation, oocytes have matured (metaphase II) and fertilization can occur. Mature oocytes have a fertile life of 2 to 4 days, perhaps longer. The

FIG 56-2
Canine breeding behavior. A, Flagging and standing. B, The postcoital tie.

time during which mature oocytes are available for fertilization has been referred to as the fertile period. Although semen is initially deposited in the cranial vagina during copulation, the large volume of prostatic fluid and the postcoital tie force semen through the cervix (see Fig. 56-2). For that reason dogs are considered among the species having intrauterine semen deposition during natural mating. Fertilization occurs in the uterine tubes. Sperm transport is enhanced by vaginal and uterine contractions that spontaneously occur with natural mating but not during artificial insemination. Freshly ejaculated canine sperm bind to the uterine crypts and glands and to the distal uterine tube, which serves as the sperm reservoir. The sperm reservoir maintains sperm viability between insemination and ovulation, regulates sperm capacitation to synchronize sperm function with ovulation, and controls sperm transport in the uterine tube. Canine sperm remain capable of fertilization in the female tract for 3 to 4 days and occasionally for as long as 6 days. Some sperm can be found in the female tract up to 11 days. The end of the fertile period is thought to be due to oocyte aging, but changes in the cervix and uterine tube environment also play a role.

# **Breeding Management**

Because of the importance of territorial and social dominance to canine reproduction, the usual practice is to take the bitch to the stud for breeding. To optimize conception rates and litter size, viable sperm that are capable of fertilization and mature oocytes that are capable of being fertilized must be present simultaneously. This can be accomplished by a number of different strategies. A common practice is to begin breeding on a predetermined day of the cycle and to breed every other day for as long as behavioral estrus lasts or for at least two breedings. Often, day 10 to day 12 after

the onset of proestrus is chosen. Because the average length of proestrus is 9 days, bitches experiencing an "average" cycle would be in estrus at that time. Because the LH surge usually occurs close to the onset of behavioral estrus, because ovulation usually occurs 2 days after the LH surge, because ova would be fertilizable 2 days later, and because freshly ejaculated semen is capable of fertilization for 4 days, this method of breeding management is usually successful. On the basis of data from artificial insemination programs, two breedings during the fertile period increase conception rates and litter size. Breeding every other day is certainly acceptable but probably unnecessary for animals with normal fertility, provided that at least two breedings are done during the fertile period.

The management scheme of breeding on a predetermined day of the cycle is often modified according to the behavior of the bitch and occasionally according to the behavior of the stud. Bitches not in estrus will not allow copulation. Putting the breeding pair together for supervised periods (15 to 60 minutes) and observing their behavior, a practice called *teasing*, will enable the manager to identify the first day of behavioral estrus; breeding can be done every 2 to 3 days thereafter throughout estrus. Certain males will occasionally show distinctly greater interest in breeding on a particular day during estrus than on other days of that cycle. Some kennel managers believe that such behavior in a male signals the optimal time for insemination, citing excellent conception rates and large litters from these males as validation.

Vaginal cytology is a very useful adjunct to these management schemes, especially in instances in which the female does not exhibit strong behavioral estrus or in which the breeding pair is separated geographically, necessitating transportation of the animals or the semen. The changes in the exfoliated cells reflect the effects of estrogen on the vaginal

epithelium. Under the influence of estrogen, the vaginal epithelium changes in thickness from a thin layer (2 or 3 cells) of stratified squamous cells without cornification to many cell layers in depth with prominent cornification and rete pegging. The epithelial cells exfoliate easily. Vaginal cytology is an excellent bioassay for estrogen that can be used to monitor the follicular phase of the ovarian cycle. As the cytologic changes in proestrus approach those characteristic of estrus, the animal or the semen should be shipped to ensure safe arrival for insemination during the fertile period. Females that do not show normal behavioral estrus during the time that the findings of exfoliative vaginal cytology are consistent with estrus (i.e., greater than 90% superficial cells) could be bred using artificial insemination.

The success of these management methods is predicated on the assumptions that ovulation will occur sometime during behavioral and cytologic estrus and that multiple inseminations will ensure that viable sperm, capable of fertilization, are present whenever ovulation and oocyte maturation actually do occur. When the LH surge is identified and used in conjunction with the other management tools, the certainty that insemination is performed during the optimal fertile period is enhanced. The practice of using the LH surge to determine when to breed has been referred to as ovulation timing. Ovulation timing is especially helpful in situations in which gamete viability is less than optimal, such as with aged bitches or when frozen-thawed semen is used. The LH surge can be identified by measuring serum LH concentrations daily or by identifying the preovulatory increase in the serum concentrations of progesterone that coincides with the LH surge in bitches. Inseminations should be done 4 to 6 days after the LH surge. Interpretation of LH and progesterone results is discussed in greater detail in the section on the assessment of reproductive hormones.

Unlike the situation with queens, breeding a bitch several times during the same day appears to offer no advantage over breeding a single time on a given day. The day of insemination with respect to the occurrence of ovulation is more important than the number of inseminations per day. As the time between insemination and the fertile period lengthens, both conception rates and pups per litter decrease. Conception rates and litter size are also affected by maternal age. Conception rates, litter size, and neonatal survival are greatest for Beagle bitches between 2 and 3.5 years of age. After 5 years of age the conception rate and litter size decline, and neonatal mortality begins to increase. Similarly, in Labrador Retriever, Golden Retriever, and German Shepherd Dog bitches studied from 1 to 10 years of age, it was found that the number of pups born declines when bitches are 7 years of age or older. Litter size differs among breeds, with the bitches of smaller breeds tending to have fewer pups per litter because they produce fewer ova.

# Diestrus

There are no external signs to mark the onset of diestrus other than the cessation of the signs of estrus. The beginning of diestrus is marked by an abrupt change in vaginal cytology. It is characterized by a sudden reduction in the number of superficial cells and the reappearance of intermediate cells, neutrophils, and background debris. Diestrus represents the luteal phase of the cycle. The serum progesterone concentration increases rapidly during the first 2 weeks after ovulation (see Fig. 56-1). It peaks at 15 to 80 ng/ml (approximately 47 to 250 nmol/L) by 15 to 30 days after ovulation. The luteal secretion of progesterone depends on pituitary LH and prolactin. The plasma progesterone concentration remains elevated but gradually declines during the next 2 months regardless of whether pregnancy occurs. In pregnant bitches there is a rapid prepartum drop in the progesterone concentration to less than 2 ng/ml (approximately 6.4 nmol/L). This occurs approximately 64 days after the LH surge and approximately 24 hours before the onset of parturition. The decline in the progesterone concentration may be more gradual in nonpregnant bitches and may not reach basal levels of 0.2 to 0.5 ng/ml (approximately 0.6 to 1.6 nmol/L) for 75 to 90 days. Specific luteotropic or luteolytic factors produced by the canine uterus or placenta that regulate ovarian CL function have yet to be identified. For example, the canine endometrium produces prostaglandin during pregnant and nonpregnant states, but this does not cause earlier CL regression in nonpregnant bitches. Although LH and prolactin are luteotropic in bitches, luteal regression appears to occur after a predetermined life span irrespective of the continuing availability of LH. Parturition and signs of false pregnancy (see Chapter 58) are the only clinical evidence of the end of diestrus. Endocrinologically, diestrus ends when the serum progesterone concentrations decline to less than 1 ng/ml (approximately 3 nmol/L).

# Anestrus

Anestrus follows diestrus and ends with the onset of proestrus of the next cycle. The interval from the end of diestrus, as defined by basal serum progesterone concentrations, to the onset of proestrus is quite variable but averages 4.5 months. Because there are no external signs associated with anestrus, this phase of the cycle has been described erroneously as a period of sexual quiescence. In fact, the pituitary-ovarian axis and the uterus are active during anestrus. Pulsatile secretion of the pituitary hormones LH and FSH continue throughout. During anestrus the endometrium sloughs. The size and activity of the endometrial glands and the thickness of the myometrium and endometrium all decrease, although not to the parameters seen in prepubertal bitches. Endometrial repair continues for about 120 days after nonpregnant cycles and for slightly longer (150 days) after a pregnant cycle. The duration of anestrus per se is rarely determined in clinical practice because anestrus has no external indicators. Rather, the interestrous interval, the onset of proestrus of one cycle to the onset of proestrus of the next cycle, is usually described. The interestrous interval is not lengthened by pregnancy or lactation.

#### THE QUEEN

Female cats are seasonally polyestrous. Cyclicity is controlled by the photoperiod, which must be approximately 12 to 14 hours of light with an intensity of 50 foot-candles. Melatonin appears to be the signal of photoperiod in domestic cats. Cats exposed to natural light usually cease cycling during short days of winter, whereas cats in equatorial photoperiods or maintained under artificial light often cycle throughout the year. It has been shown that maintaining 14:10 to 16:8 hour light: dark schedules maximizes the number of cycling queens in the colony. In the presence of adequate light, sexual maturity and the first estrous cycle normally occur at 6 to 9 months of age, with a range of 5 to 12 months. Unlike bitches, which ovulate spontaneously, queens are induced to ovulate by coital stimulation of the vagina. In addition to coitusinduced ovulation, many domestic cats also have cycles in which spontaneous ovulation occurs.

The follicular phase of the cycle is characterized by increasing serum concentrations of estradiol 17- associated with the onset of proestrus and estrus. Because there is negligible vulvar swelling or discharge in queens compared to bitches, proestrus and estrus are usually recognized by behavioral changes. When it is observed, the vulvar discharge is a clear fluid. Proestrus is characterized by rubbing, treading with the rear feet, vocalization, and decreasing hostility toward the male, although queens will continue to strike at the tom. Proestrus may be so short as to be unrecognized, but more typically it lasts 1 to 2 days.

Estrus is characterized by increased vocalization, rolling, lordosis, holding the tail to one side, and allowing copulation. The characteristic estrual posture can sometimes be elicited by stroking the perineum (Fig. 56-3). Tremors of the body or tail may also be seen. The cytologic appearance of exfoliated vaginal epithelial cells during the estrous cycle is similar to that of bitches, except that red blood cells are much less common. The duration of estrus among queens is quite variable but averages 5 to 8 days. Its duration is not influenced by copulation. Anovulatory cycles occur every 2 to 3 weeks (average 18 days with 12 hours of light) as long as light is adequate. There may or may not be a short *interestrous* period of a few days.

Ovulation occurs as a result of a neuroendocrine reflex that is initiated by the mechanical stimulation of sensory

FIG 56-3
Estrual posture of the queen.

receptors in the vagina and cervix. This sensory input causes a surge of LH to be released from the pituitary gland (Fig. 56-4), which in turn causes ovulation. A high level of estradiol is also required for ovulation. The precise intensity of the copulatory stimulation necessary to induce the LH surge is unknown but varies among queens. The frequency of coital stimulation is apparently the single most important determinant of ovulation in cats. A single copulation induces the LH surge necessary for ovulation in approximately 50% of cats, whereas more than 90% of normal domestic shorthair cats ovulate if bred 3 times daily for the first 3 days of estrus. The day of estrus on which mating occurs and the duration of estrus have no apparent effect on ovulation, except insofar as the concentration of estradiol varies. Once the LH surge occurs, hormonal responses to additional copulatory stimuli are diminished. Ovulation occurs approximately 48 hours after the LH surge. Although cats continue to be referred to as induced ovulators, it is also clear that many cats (35% to 60%) also ovulate spontaneously, in the absence of coital stimulation or direct physical contact with other cats.

After intromission and ejaculation, the queen emits a characteristic scream that signals to the male to dismount. Despite willing acceptance of copulation moments before, queens will attack the tom at this time. Because cats often prefer seclusion, breeding may not be witnessed by the owner. The queen's scream may be the only evidence that mating has occurred. The queen then begins frenzied rolling and grooms her perineum for several minutes and aggressively rebuffs the male. When this "after-reaction" subsides, the queen allows another mating, by either the same tom or another one. Mating frequency is greatest during the first 2 hours (average of five copulations per hour), after which the frequency decreases to about one copulation per hour for the next 3 days. To ensure adequate copulatory stimulation to induce ovulation, three breedings per day for the first 3 days of estrus are recommended. Semen is deposited in the vagina during copulation. The cervix and uterotubal junction are barriers to sperm transport in the cat. The cervix is open on the first day of estrus in both ovulatory and nonovulatory cycles. It is closed when estradiol concentrations fall and when progesterone concentrations rise. As with the bitch, the queen's uterine contractions during mating promote sperm transport. The uterotubal junction and uterine crypts are sperm reservoirs before ovulation, and the tubal isthmus is the reservoir near ovulation.

Because of the territorial nature of cats, especially males, the queen should be brought to the stud. The two should be placed together for short periods so that their behavior can be observed. In this way the manager can be confident that matings have occurred; conversely, the cats can be separated if fighting occurs. This supervised mating scheme may be the best way to optimize conception, but it is labor intensive. Some managers prefer to house the queen and tom together and allow mating to occur ad libitum, without direct observation. In some large breeding colonies, harem, rather than individual, mating schemes are used. In the harem scheme,

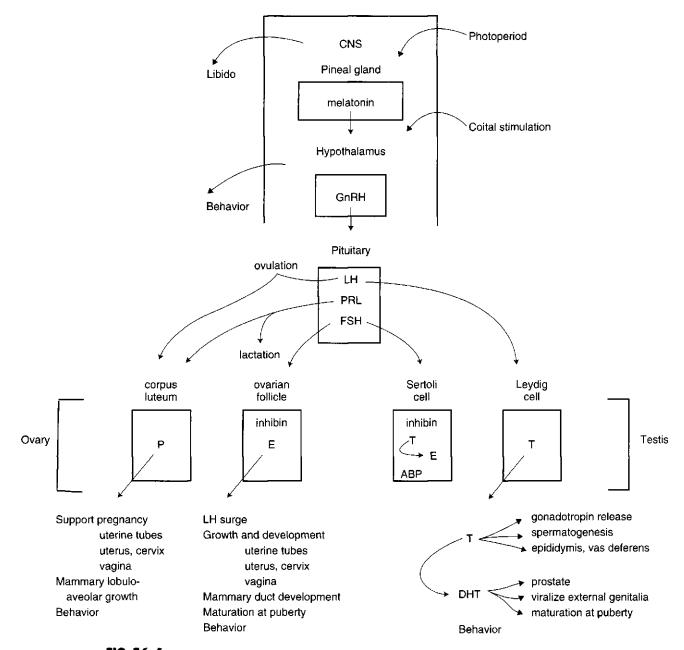

FIG 56-4
Hypothalamic-pituitary-gonadal axis. ABP, Androgen-binding protein; DHT, dihydrotestosterone; E, estrogen; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; P, progesterone; PRL, prolactin; T, testosterone.

one or two toms are housed with several queens. Even though both toms have equal access to the queens, the dominant male usually does most of the breeding. This method is the least labor intensive but has the disadvantages of unknown breeding dates, unknown paternity if more than one tom is involved, and delayed recognition of subfertility in individual animals.

After ovulation the follicles luteinize and produce progesterone. This is the luteal phase of the cycle. Serum concentrations of progesterone rise 24 to 48 hours after ovulation and peak 25 to 30 days later. As with bitches, luteal progesterone is necessary for the maintenance of pregnancy. The corpora

lutea continue to produce progesterone throughout the approximately 65-day gestation (Fig. 56-5), with the serum concentrations gradually declining during the second half of pregnancy. Contrary to what was previously thought, the feline placenta either does not secrete progesterone or does so in amounts insufficient to maintain pregnancy. Serum concentrations of estradiol increase in late pregnancy in cats. Although estrous behavior has been observed in pregnant queens, true superfetation has not been proved.

There apparently are pregnancy-specific luteotropic hormones from the feline placenta or pituitary that control the life span of the corpus luteum. After the nonfertile induction

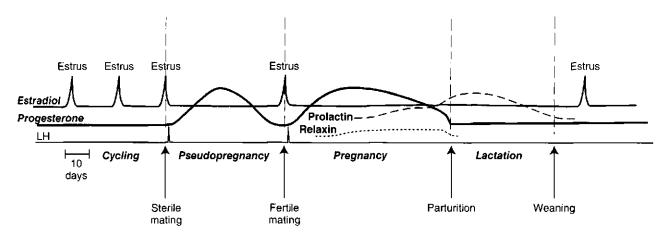

FIG 56-5
The feline estrous cycle.

of ovulation (i.e., when the animal is not pregnant), the corpora lutea persist for about 30 to 40 days. The next cycle may begin any time thereafter, usually within 10 days. In one colony the average interestrous interval was 61 days in queens that were bred but did not conceive, whereas the average interestrous interval for nonbred, anovulatory queens was 22 days. Serum concentrations of progesterone were not determined in those cats.

Litters typically consist of two to five kittens. Queens usually do not resume cycling while they are nursing a litter. Estrous behavior is usually evident 2 to 3 weeks after weaning, although this is quite variable. The postpartum estrus is shorter in duration and less fertile than others. Litter size and neonatal survival are best for queens age 1 to 5 years, provided that first parity occurs before 3 years of age. Litter size and neonatal survival usually improve after the first parity. However, if the first parity occurs after 3 years of age, litter size and neonatal survival usually remain poor. Reproductive performance declines after 6 years of age. Because of decreased fertility, decreased litter size, increased neonatal losses, and the increased prevalence of other illnesses in older queens, most should be retired from breeding after 8 years of age.

# DIAGNOSTIC TESTS FOR THE REPRODUCTIVE TRACT

#### **VAGINAL CYTOLOGY**

The importance of exfoliative vaginal cytology in breeding management and in the evaluation of females with reproductive disorders cannot be overemphasized. Vaginal cytology is used to determine the stage of the estrous cycle, determine breeding and whelping (see Chapter 58) dates, and identify the nature of certain abnormal processes within the reproductive tract (see Chapter 57). Specimens may be obtained with a moistened, cotton-tipped swab or by flushing and aspirating a small volume of saline solution from the vagina. Specimens can be stained with any

number of commercially available stains, including Wright's, Wright-Giemsa, modified Wright-Giemsa (Diff-Quik; Baxter Scientific), trichrome, or new methylene blue. The number and morphologic characteristics of vaginal epithelial cells are evaluated. The preparations are also examined for the presence of other material, such as bacteria, white blood cells, red blood cells, mucus, cellular debris, endometrial cells, or neoplastic cells.

The vaginal epithelium changes dramatically under the influence of estrogen, a process known as cornification. During early proestrus the noncornified parabasal and intermediate vaginal epithelial cells are the predominant cells (more than 80%). As proestrus progresses, the population of exfoliated cells gradually matures; parabasal and intermediate cells disappear as superficial (cornified) cells increase in number. At the end of proestrus superficial and anuclear squamous cells account for 70% to 80% of the epithelial cells. White blood cells decrease in number. Extracellular bacteria may be present throughout proestrus and estrus (Fig. 56-6).

A predominance of superficial cells, an absence of neutrophils, and a clear background characterize vaginal cytologic specimens obtained during estrus. During estrus 90% or more of the epithelial cells are superficial and anuclear squamous cells. White blood cells are normally absent during estrus. Red blood cells and extracellular bacteria are often present (see Fig. 56-6). The beginning of diestrus is marked by an abrupt change in vaginal cytology. Diestrus is characterized by a sudden reduction in the number of superficial cells and the reappearance of intermediate cells, neutrophils, and background debris. On the first day of cytologic diestrus, parabasal and intermediate cells outnumber the superficial and anuclear squamous cells. Sheets of intermediate cells are also often observed. White blood cells return in high numbers during the first day or two of diestrus. Red blood cells and bacteria disappear. The initial dramatic change in cytologic appearance is followed by a gradual change to the anestrual cytologic appearance. On the basis of the examination of only a single cytologic specimen, proestrus cannot

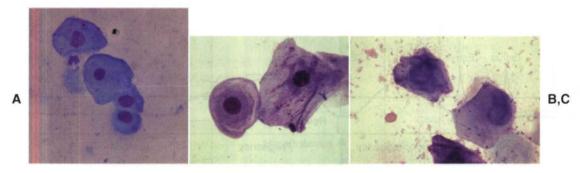

FIG.56-6
Vaginal cytology of estrus. **A**, parabasal and intermediate cells. **B**, Intermediate and superficial cells. **C**, Anuclear squamous cells.

necessarily be distinguished from diestrus. The vaginal cytology of anestrus is quite acellular; it contains primarily parabasal cells and a few small intermediate epithelial cells. The transition from proestrus, through estrus, and into diestrus is usually adequately monitored by cytologic studies done every 2 or 3 days.

#### VAGINOSCOPY

Vaginoscopy is useful for evaluating animals with lower urinary tract signs or urinary incontinence, vulvar discharge, infertility, and anatomic abnormalities; for determining the nature and extent of lesions within the vestibule and vagina; and for identifying the stage of the estrous cycle. Samples for cytologic, microbiologic, and histopathologic studies can easily be obtained through the endoscope. Assuming that the clinician has access to the proper equipment, laser surgery can also be performed. Complications resulting from vaginoscopy, which include hemorrhage, laceration, and introduction of infection, are uncommon with proper technique. Endoscopic findings are assessed by comparing them to the normal anatomic features of the vagina, often in conjunction with vaginal cytology. The endoscopic appearance varies tremendously with the stage of the estrous cycle.

The canine vagina is quite long. In Beagles, for example, it measures 10 to 14 cm in length and 1.5 cm in diameter, whereas in Newfoundlands the length may be up to 29 cm. The endoscopic equipment must be of the appropriate size for the particular female. Proctoscopes and cystoscopes designed for human pediatric or adult patients or flexible fiberoptic endoscopic equipment of appropriate diameter can be used. Pediatric anoscopes or veterinary otoscopes may be narrow enough for use in queens and small bitches but are too short for examination of the cranial vagina and cervix.

In bitches that are in heat, vaginoscopy is usually performed with the animal awake and standing and without sedation or anesthesia unless a biopsy is planned. Anesthesia is necessary for vaginoscopy in queens, small bitches, and puppies and when cystoscopes with saline infusion to distend the vagina will be used. The perineum is inspected and cleansed. The endoscope is then lubricated with warm saline solution or with sterile, water-soluble lubricant. The clitoris

FIG 56-7 Vaginoscopy demonstrating the vestibulovaginal junction in a 1-year-old, spayed female retriever with lympho-nodular urethritis causing persistent pollakiuria.

and clitoral fossa must be avoided. Therefore the endoscope is passed in a dorsal direction through the dorsal commissure of the vulva. There will be increased resistance at the narrow vestibulovaginal junction (Fig. 56-7) in all but estrual bitches. It is especially narrow in prepubertal and neutered animals. The angle of the speculum is adjusted to be more parallel with the spine after it passes through the vestibulovaginal junction.

During proestrus the longitudinal folds of the vagina are edematous, round, and smooth. As new folds develop, the vaginal lumen becomes filled with folds. A clear, bright-red fluid is seen in the vaginal lumen, sometimes in large amounts. As estrus approaches, the vaginal folds become lower and wrinkled. During estrus the folds appear sharp, angular, and crinkled. The mucosa is pale, and the vaginal lumen is wide. There is less luminal fluid than there is during proestrus. This fluid is clear and usually straw colored; however, it may continue to be bright red throughout estrus.

During diestrus (the luteal phase) the vaginal folds are low, round, and soft. The folds in the cranial vagina have a characteristic rosette appearance and may be mistaken for the cervix. Clear or opalescent mucus is present in the vaginal lumen during diestrus. The vaginal mucosa has streaks of hyperemia. During anestrus and in neutered bitches, the vaginal folds are low and round and do not fill the lumen. There is a thin mucous coating that gives the mucosa a translucent, pink-red appearance. In these animals the mucous membranes are thin and easily traumatized. Pinpoint submucosal hemorrhages may develop in response to seemingly gentle contact with the endoscope. During anestrus and in neutered animals there is usually some resistance to the passage of the endoscope unless the instrument is very well lubricated.

In bitches one of the vaginal folds, known as the *dorsal median postcervical fold*, is often mistaken for the cervix. This fold extends from the caudal-dorsal edge of the vaginal portion of the cervix along the dorsal midline and eventually blends into lesser folds of the vagina. It is composed of longitudinal and oblique smooth muscle bundles and irregularly arranged collagen. Unlike other folds of the vagina, the dorsal median fold has no elastic fibers. In Beagle-size bitches, this fold is 15 to 42 mm long and 2 to 10 mm wide, compared with the average vaginal length in the same bitches of 158 ± 30 mm. The lumen of the cranial vagina in this area is quite narrow. Because of its length, location, and inelastic nature, the dorsal median postcervical fold often prevents visualization and catheterization of the canine cervix.

The vaginal portion of the cervix is tubular, with small furrows radiating from the os, which give it the appearance of a star or rosette. The cervical os is not obviously "open," even if fluid is seen flowing through it, except during the puerperium. The vaginal lumen around the cervix and the cranial aspect of the dorsal median postcervical fold is quite narrow, and except during estrus the use of small-diameter (0.5 cm) instruments is usually necessary to visualize the cervix. The narrow pericervical vaginal lumen with the dorsal median postcervical fold and the rosette appearance of the cranial vagina can be confused with the cervix.

#### VAGINAL BACTERIAL CULTURES

Bacterial infections of the reproductive tract are relatively common. Bacterial culture is indicated for the evaluation of many reproductive disorders, including infertility, vulvar discharge, pyometra, metritis, abortion, and stillbirth. Because the uterus is usually sterile, except in some bitches during proestrus and estrus, the interpretation of uterine culture results is relatively straightforward. Unfortunately, because of the difficulty in catheterizing the cervix in the bitch or queen, uterine samples are usually obtained only during laparotomy. Vaginal cultures are usually performed in lieu of uterine cultures. To minimize contamination from the vestibule and caudal vagina, samples for bacterial culture should be obtained from the cranial vagina using a guarded culture swab (e.g., those manufactured by Kalayjian Industries and Nasco) or through a sterile speculum.

Bacteroides

Enterococcus

Peptostreptococcus (hemolytic and nonhemolytic)

Ureaplasma

The canine vagina has normal bacterial florae, which are listed in Box 56-1. Only 2% of 826 specimens obtained from intact bitches were negative for bacterial growth (Bjurström et al., 1992), whereas 23% of 66 specimens from queens were negative (Ström-Holst et al., 2003). In order of reported frequency, the most commonly isolated organisms from bitches are Pasteurella, Streptococci, and Escherichia coli. With the exception of Mycoplasma, anaerobic organisms are much less commonly isolated than aerobic. Cultures from bitches usually yield mixed populations of bacteria; however, in Bjurström's study 18% were a growth of only one organism. The florae vary within and among individuals and throughout the cycle. The normal florae of the feline vagina are similarly diverse. E. coli, Staphylococcus, and Streptococus canis are the most common organisms recovered from queens. Unlike the situation in bitches, a single organism (most often E. coli) is isolated from 41% of cats. Anaerobic organisms are uncommon in queens. Even in normal bitches and queens, organisms may be recovered in large numbers.

Most of the organisms that make up the normal vaginal florae are also potential pathogens. Several studies have shown that there are no differences among the bacterial isolates from normal fertile bitches, infertile bitches, and bitches with evidence of genital disease. Isolation of opportunistic pathogens from the vagina is therefore not proof of infection. Thus the results of vaginal cultures and the potential role of the isolated organisms in the pathogenesis of the clinical signs must be interpreted cautiously. *Brucella canis* (see Chapter 58) is always considered a pathogen, even in the absence of clinical signs. The role of *Mycoplasma* spp. and *Ureaplusma* spp. in reproductive disorders in cats and dogs remains unclear.

## **VIROLOGY**

Viral diseases may cause reproductive problems by directly affecting reproductive organs or because of the systemic illness they cause in the pregnant female. Respiratory disease and neonatal death are the most common manifestations of canine and feline herpes infection. Canine herpes virus also causes apparent failure to conceive; abortion; and, less commonly, genital lesions. Rarely, vesicular lesions may be found on the mucosa of the vestibule or prepuce of infected dogs. The most important route of transmission is oronasal contact with infected secretions. Transplacental and venereal transmission are much less important. The virus may be isolated from nasal, conjunctival, tracheal, vaginal, or preputial scrapings for 2 to 3 weeks after acute infection. Thereafter virus isolation and polymerase chain reaction (PCR) are usually negative. Because canine herpesvirus is poorly immunogenic, virus-neutralizing antibodies are present in small amounts for short periods. The finding of any detectable titer in the presence of compatible clinical signs is therefore considered significant. Fetal and neonatal necropsy findings are generalized, multifocal hemorrhages in kidney, lung, and liver and necrotic foci with intranuclear inclusion bodies. In queens panleukopenia, calici virus, feline infectious peritonitis, and feline leukemia virus infection are reported to be potential causes of infertility, abortion, and neonatal death.

# ASSESSMENT OF REPRODUCTIVE HORMONES

Measurement of serum concentrations of reproductive hormones can be useful in evaluating animals with suspected or known reproductive disorders. The reproductive hormones are released in cyclic, episodic, or pulsatile manners; therefore the results of a single determination often are not diagnostic because the phase of the cyclic release at the time of sample collection is unknown. For that reason, repetitive determinations performed over the course of hours, days, or weeks, or provocative testing, may be necessary. Most hormone assays, such as radioimmunoassays (RIA), chemiluminescent, and enzyme-linked immunosorbent assays (ELISA), depend on immunologic reactions. Errors can result if antibodies or antigens in homologous assay systems are not species specific and if species-specific interference with antibody binding occurs in heterologous systems. For these reasons, it is critical that each laboratory validate its procedures and determine reference ranges for each species and each hormone to be tested.

# **Progesterone**

As the time of ovulation approaches during estrus, ovarian follicular cells transform from estrogen-producing to progesterone-producing cells. LH causes ovulation and thus is responsible for this transformation. After ovulation, the follicles become CLs and produce progesterone. The stage of the ovarian cycle during which progesterone concentrations are high is called diestrus. If conception occurred, the length of diestrus will be the length of gestation. Gestation averages 65 days after breeding in the queen and 63 days after breeding in the bitch. If conception did not occur in a queen that did ovulate, the CLs will regress in 30 to 40 days. The bitch, on the other hand, is unique among common domestic animals in that the CLs persist and produce progesterone for 60 or more days, irrespective of pregnancy status. The CLs are the only significant source of progesterone in the pregnant bitch and queen and are required to maintain pregnancy throughout. Progesterone concentration must drop to basal levels for parturition to occur. It remains at basal levels through anestrus, until ovulation during the next estrous cycle (see Fig. 56-1).

In the bitch progesterone concentrations begin to increase above basal levels as a preovulatory event. This initial rise occurs simultaneously with the LH surge. Therefore progesterone can be used to approximate the LH surge and predict impending ovulation in the bitch. In the queen the initial rise above basal progesterone concentration occurs after the LH surge. In both the bitch and queen, high progesterone concentrations are indicative that ovulation did occur. The next cycle will not begin until sometime after progesterone has returned to basal levels.

There are a wide variety of laboratory methods used to detect progesterone. These include RIA, which is considered to be the gold standard, and chemiluminescent immunoassay (CLIA). These are available from several commercial laboratories with "same-day" results. Lower values are obtained using CLIA than RIA. Results may be reported in ng/ml or nmol/L. The conversion from one unit to the other is (ng/ ml)(3.18) = (nmol/L) of progesterone. It is essential to use the reference ranges established by the laboratory for its methodology and validated for use in the particular species. The advantage of RIA and CLIA is quantitative results. There are point-of-care tests based on ELISA and rapid immunomigration (RIM) method (Ovucheck® Premate, Synbiotics Corp.). These provide semiquantitative results in three ranges. The low range is usually less than 3 ng/ml (less than approximately 9.5 nmol/L), the midrange is from approximately 3 ng/ml to 10 ng/ml, and the high range is greater than approximately 10 ng/ml (approximately 31.8 nmol/L), depending on the kit manufacturer. The midrange of the kit is designed to correlate with the LH surge in the bitch and is used to predict that ovulation will occur in 3 to 6 days. Compared with RIA or CLIA, the semiquantitative, in-house kits have been found to be 80% to 90% accurate in determining progesterone concentrations in dogs and cats. Nevertheless, some practitioners find them useful. Storage time, temperature, contact with red blood cells, contact with serum

separator gel, and anticoagulants affect the results. Therefore the laboratory or kit manufacturer's recommendations for sample handling must be followed. Samples for progesterone determination must never be drawn into serum separator tubes because the results will be spuriously decreased.

One of the most common reasons to measure progesterone in bitches is to determine the optimal time to breed. It is used in two ways. One is to approximate the time of the LH surge, a practice known as ovulation timing. It is based on the fact that in bitches the serum progesterone concentration increases to more than 1 to 2 ng/ml (approximately 3 to 6 nmol/L) at or shortly before the preovulatory LH surge. Therefore serial determinations (every 2 to 3 days) of the serum progesterone concentration during proestrus, to identify the initial increase above 2 ng/ml, can be used to estimate the time of ovulation, which follows the LH surge by about 2 days. As discussed earlier, fertilization could occur about 2 days after ovulation. Therefore the recommendation is to breed 3 to 6 days after the initial rise in progesterone (i.e., the LH surge) is detected. The other way progesterone concentrations are used to determine breeding day is based on the knowledge that fertilization could occur about 2 days after ovulation, during which time progesterone concentration has been rapidly increasing. Serum concentrations of progesterone greater than 8 ng/ml (25.4 nmol/L) are interpreted to indicate that ovulation has occurred. Analysis of several independent breeding trials in which serum concentrations of progesterone were determined on the days of insemination revealed that pregnancy rates were best when insemination was performed on days that serum progesterone concentrations were greater than 8 ng/ml (greater than 25.4 nmol/l) and up to 19 to 26 ng/ml (approximately 60 to 80 nmol/L). Two inseminations, 48 hours apart, are recommended, unless the initial progesterone is already near 19 ng/ ml (60 nmol/L), in which case the second insemination is done the next day.

Finding the increased serum concentrations of progesterone indicative of ovulation would be of interest in females suspected of having ovulation failure. In the case of queens this may be due to inadequate copulatory stimulation to induce the LH surge. Finding high progesterone would also confirm ovulation in an animal suspected of having had a "silent" or unobserved heat, or it could confirm the presence of an ovary in an animal suspected of having an ovarian remnant after being spayed. The adequacy of luteal function during pregnancy can be monitored by determining serum progesterone concentrations once weekly for about 9 weeks after breeding or until parturition. This would be of interest in females in which inadequate luteal function (premature luteolysis; hypoluteoidism) was the suspected cause of unexplained abortion. It would also be useful in monitoring the effectiveness of certain abortifacient drugs. In pregnant bitches (but not necessarily in pregnant queens), parturition normally occurs within 24 hours after serum progesterone concentration decreases below 1 to 2 ng/ml (approximately 3 to 6 nmol/L). Therefore impending parturition can be predicted by monitoring the serum progesterone concentration.

BOX 56-2

### Indications for Measuring Serum Progesterone

#### Ovulation timing

- Identify LH surge, breed 3 to 6 days later
- Identify fertile period, progesterone approximately 10 to 26 ng/ml

#### Infertility

- Confirm that ovulation did (high progesterone) or did not (low progesterone) occur
- High progesterone would be found in cases of luteal cyst
- Confirm that induction of ovulation was successful Assess corpus luteum function
- Monitor the effectiveness of certain abortifacient agents
- In cases of spontaneous abortion, assess for premature luteolysis or hypoluteoidism
- · Identify that a "silent" heat occurred
- Identify ovarian remnant, high progesterone 5 to 7 days after signs of heat

#### Predict whelping

- Within 24 hours of progesterone less than 2 ng/ml
- 65 ± 1 day from the LH surge

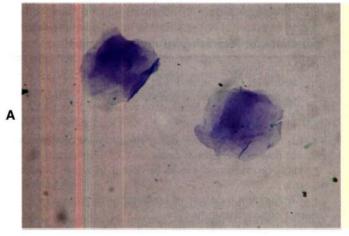

Recognize progesterone-producing testicular tumor

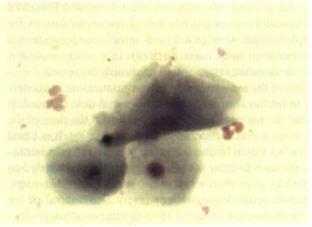

This information would be of use in the management of dystocia and in the planning of cesarean sections (Box 56-2).

#### **Estradiol**

Estradiol-17 $\beta$  is the main estrogen in circulation. The primary source of estradiol in sexually intact females is the ovarian follicle. In both males and females estradiol is also derived in peripheral tissue by the aromatization of testosterone and androstenedione. In sexually intact males the testis produces small amounts of estradiol, but this accounts for only about 20% of estradiol production in dogs. The majority is derived from aromatization of circulating androgens, testosterone and androstenedione. Androstenedione is of adrenal origin. Typical mean serum estradiol concentrations in the bitch are 5 to 10 pg/ml during anestrus, 10 to 20 pg/ml during early proestrus, and 50 to 100 pg/ml during late proestrus. Estradiol concentrations decline through estrus (see Fig. 56-1). During estrus in queens, estradiol is also typically >25 pg/ml to above 50 pg/ml. It returns to basal levels of <15 pg/ml in between cycles and during the seasonal anestrus.

Unfortunately, estradiol concentrations are often at or below the limits of detection of the assays used by many commercial endocrine laboratories. Estradiol concentrations also fluctuate widely and rapidly, and the high concentrations that occur during proestrus may be detectable for only a day or two. Deficiencies in circulating concentrations of estradiol are rarely documented in dogs and cats. Pathologic increases in estradiol production, such as those that occur in animals with ovarian follicular cysts or Sertoli cell tumors,

**FIG 56-8 A,** Vaginal cytology from an 18-month old cat with an ovarian remnant after being spayed 1 year ago. Estrus cycles began a month ago. **B,** Preputial cytology from a 10-year-old, male retriever with an estrogen-producing interstitial cell tumor.

may still be less than the detectable limits of many assays. For these reasons the measurement of estradiol concentrations often does not yield diagnostic results. A simple, accurate means of gauging estrogenic activity in the female is to evaluate vaginal epithelial cells for signs of cornification (see Fig. 56-6). All things considered, vaginal cytology is often preferable to determination of serum concentrations of estradiol in females. The preputial epithelium is also responsive to estrogen, exhibiting changes similar to those of the vaginal epithelium (Fig. 56-8). The paraneoplastic syndromes associated with excessive estrogen in dogs include alopecia, gynecomastia, pendulous prepuce, and bone marrow suppression. In bitches and queens cystic follicles in intact or remnant ovaries may continuously produce estradiol and cause persistent signs of heat and, much less commonly, alopecia. Assessing estradiol or its influence on vaginal epithelium is indicated for determining the stage of the estrus cycle for breeding management and for evaluating females suspected of having an ovarian remnant after being spayed. Finding cornification of vaginal epithelium or very high estradiol concentrations in a supposedly spayed queen or bitch that is displaying characteristic physical or behavioral signs of heat would be consistent with a diagnosis of ovarian remnant. Finding very high estradiol concentrations or the influence of estradiol on vaginal or preputial epithelium in an animal displaying estrogen-induced paraneoplastic syndromes justifies a search for a gonadal source (estrogen-producing testicular tumor, cystic ovarian follicles) or an exogenous source of estrogen. These would be far more likely than an adrenal source of estrogen in species other than the ferret.

# Gonadotropins: Follicle-Stimulating Hormone and Luteinizing Hormone

The gonadotropins, FSH and LH, are produced by the pituitary, under the control of hypothalamic gonadotropin-releasing hormone (GnRH; see Fig. 56-4). As discussed

earlier in the chapter, they are secreted in a pulsatile manner, in ever-increasing magnitude until a so-called surge occurs. The increasing concentrations of FSH at the end of anestrus initiate ovarian follicular development and the onset of the next estrus cycle. The surge of LH causes maturation and ovulation of ovarian follicles, which luteinize and produce progesterone. The duration of the LH surge is relatively short, usually occurring within a 24-hour window, although it may remain elevated for somewhat longer. Additionally, in queens a neuroendocrine reflex initiated by coital stimulation of the vagina also causes the LH surge. In males FSH supports Sertoli cell function and spermatogenesis. LH stimulates testosterone secretion by the Leydig cells of the testis. The gonadal hormones, in turn, feed back to the hypothalamus and pituitary. Following gonadectomy this negative feedback control of LH is lost, and serum concentrations of LH and FSH are persistently elevated. This could also occur with the rare condition of gonadal dysgenesis. The secretory capacity of the pituitary gonadotropins can be assessed by determining LH and/or FSH before and after administration of GnRH. A point-of-care, semiquantitative immunochromogenic assay for LH has been intermittently available (ICG Status-LH®, Synbiotics). Few commercial laboratories offer quantitative assays for LH or FSH for veterinary patients at this time.

As discussed earlier, identification of the preovulatory LH surge is a useful tool in canine breeding management; however, the LH surge lasts only 24 to 72 hours. Therefore frequent sampling (i.e., at least once q24h) is essential to ensure that it is not missed. Because pulses of LH other than the surge may be of sufficient magnitude to be detected by the assay, some clinicians recommend measuring serum concentrations of progesterone several days after the surge. Progesterone concentrations above 2 ng/ml (6 nmol/L) differentiate the actual pre-ovulatory LH surge from the normal proestrus pulses of LH. Trying to determine optimal breed-

ing time with such precision is most applicable when frozen semen is to be used because the life span of thawed spermatozoa is short, perhaps only 24 hours. Because the frequent blood sampling necessary to identify the LH surge is inconvenient and expensive, progesterone concentrations are often assessed in lieu of LH itself to estimate the surge.

To avoid unnecessary laparotomy, serum concentrations of LH can be measured to determine the presence or absence of gonads in animals with unknown reproductive status, such as those newly acquired by shelters or private owners. High concentrations of LH are consistently found from 5 days to as long as 5 years after ovariectomy in bitches. This is because negative feedback from the gonadal hormones to the pituitary is lost. Conversely, LH is also helpful for evaluating females suspected of having ovarian remnants after being spayed. In this situation feedback loops are still intact and LH concentrations will be low except during heat. Finding high serum LH concentrations is sensitive for detecting animals that have been spayed (sensitivity: 100% in 50 queens; 98% in 300 bitches). However, it is not as specific, especially in bitches, because high LH is also normally found in cycling females (specificity: 92% in queens; 78% in bitches). The proportion of animals with high LH that are spayed—in other words, the probability that high LH correctly predicts a spayed animal—is fairly high (positive predictive value: 92% in queens; 90% in bitches) but not perfect, again because intact females also have high LH at some times during the estrus cycle. Therefore females with high LH are either spayed or in heat, which can easily be differentiated by physical examination, vaginal cytology, or measurement of serum progesterone. Males with high LH have been castrated. The proportion of animals with low LH that are actually spaved is very low (negative predictive value: 100% in queens; 96% in bitches). In other words, the probability that finding low LH will correctly predict an intact animal is very high. Females with low LH have not been spayed or have ovarian remnants and are not presently in heat. Males with low LH have one or both testicles. If they are not in the scrotum, the male is cryptorchid. A much less likely cause of low LH in males and females would be exposure to exogenous sex hormones.

FSH is rarely measured in small animal practice, primarily because appropriate assays are usually not commercially available. However, it has been shown that FSH is a more specific indicator of neuter status than is LH in bitches because FSH concentrations are consistently higher in spayed bitches than intact bitches, even during heat.

# **Gonadotropin-Releasing Hormone**

GnRH, which is secreted by the hypothalamus, controls pituitary secretion of FSH and LH in both male and female animals. GnRH assays are not readily available, and GnRH is rarely measured in the small animal practice. However, exogenous GnRH administration can be used to evaluate the pituitary-gonadal axis. After the administration of GnRH to normal dogs and cats, there is a prompt (within 30 minutes) increase in the serum concentrations of LH. The magnitude

of the response is influenced by the stage of the reproductive cycle and the dose of the drug. After the serum concentration of gonadotropins increases in response to GnRH, serum concentrations of gonadal hormones also increase. The degree of gonadal responsiveness understandably varies with the stage of the reproductive cycle in females and whether the male has one, two, or no testes. Failure of serum LH concentrations to increase after GnRH administration points to the possibility of a pituitary problem. Failure of gonadal sex hormones to increase appropriately after GnRH administration indicates either pituitary dysfunction (no increase in LH), gonadal dysfunction, or prior gonadectomy. Administration of GnRH can also be used to induce estrus in the bitch and queen.

# Relaxin

Relaxin is produced primarily by the placenta; therefore it is pregnancy specific in bitches and queens. In pregnant bitches and queens, relaxin reaches detectable levels in serum or plasma as early as 20 days after the LH surge and peaks 30 to 35 days after the LH surge. It remains high throughout pregnancy, until parturition or abortion, when it declines precipitously. Low levels may be detectable for 4 days postpartum in bitches. Although the manufacturer suggests that the test can be useful 21 days after breeding, it is a more sensitive indicator of pregnancy when performed 30 or more days after breeding. There may be an influence of litter size on relaxin concentrations. Finding high concentrations of relaxin in serum or plasma confirms pregnancy. Declining or undetectable concentrations are found in cases of spontaneous or induced abortion and after parturition. Relaxin is undetectable in pseudopregnant and nonpregnant bitches and queens. There are two commercially available point-ofcare assays for relaxin. Witness Relaxin®, a rapid immunomigration assay, can be used for dogs and cats. ReproCHEK® is an ELISA system for use in dogs. (Both assays are from Synbiotics Corp.)

### DIAGNOSTIC IMAGING

Radiology and ultrasonography are useful for evaluating the ovaries, uterine wall, and intrauterine contents; confirming pregnancy; and assessing fetal viability. The normal uterus and ovaries in a nonpregnant animal are not detected by routine abdominal radiography (see Fig. 56-9). During normal anestrus they may be difficult to identify by ultrasonography. Increased size and density and an abnormal shape of the uterus may be detected by either technique. Ultrasonography can be used to evaluate the uterine wall and the intrauterine contents. Ultrasonography may also help identify ovarian remnants, ovarian cysts in animals with persistent estrus and hyperestrogenism (follicular cysts), or persistent anestrus (nonfunctional or luteal cysts). It may be able to identify ovarian neoplasia as well. In males diagnostic imaging is very helpful in evaluating the prostate and testes (see Chapters 61 and 62). Negative findings with diagnostic imaging do not necessarily exclude disease in the reproductive tract, especially in females.

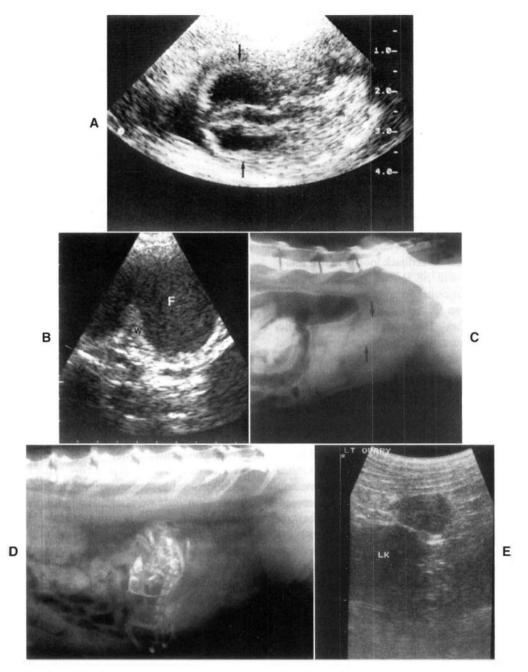

FIG 56-9

**A,** Sonogram of canine gestational sac (arrows) at 29 days. Scale is in centimeters. **B,** Sonogram of canine pyometra showing thickened uterine wall (W) and lumen distended with fluid (F). **C,** Radiograph of feline pyometra showing fluid-filled uterus (arrows). **D,** Radiograph of mummified fetus. **E,** Sonogram of 1.8 × 1.2-cm ovary with corpora lutea in a normal 3-year-old Weimaraner 30 days after estrus. The serum progesterone concentration was 64 nmol/L. LK, Left kidney. (**A** Courtesy Dr. Tom Bell, East Lansing, Mich.)

Because of the difficulty involved in catheterizing the cervix, contrast studies of the uterus and uterine tubes (i.e., hysterosalpingography) are rarely done in bitches and queens. During estrus contrast material deposited in the cranial vagina may enter the uterus and provide a hysterogram, but at other stages of the cycle the cervix is normally closed. Positive-contrast vaginography, using a Foley catheter and a water-soluble contrast agent (e.g., diatrizoates such as

Renografin®), is easily performed, but general anesthesia is necessary. Vaginography can be considered if vaginoscopy fails to clearly identify strictures, anatomic defects, masses, or foreign material in the vagina.

# **KARYOTYPING**

Some intersex conditions and developmental abnormalities of the reproductive tract may be associated with chromo-

somal anomalies (e.g., XXX, XO). These animals are usually seen because of abnormal external genitalia, infertility, or persistent anestrus. Karyotype analysis can be performed if a congenital rather than an acquired cause is suspected and if routine diagnostic tests have failed to identify the cause of the reproductive dysfunction. Cells from any tissue can theoretically be used for chromosomal analysis, but lymphocytes from heparinized blood samples are the usual specimen. (e.g., University of Minnesota Veterinary Cytogenetics Laboratory, Department of Veterinary Pathobiology).

# LAPAROSCOPY AND CELIOTOMY

Exploratory celiotomy is often the most cost-effective way to diagnose and treat intersex animals. In all other circumstances, however, diagnostic laparoscopy or exploratory celiotomy should not be done until a noninvasive diagnostic evaluation of the bitch or queen with a reproductive disorder has been completed. Laparoscopy and celiotomy allow gross visualization of the reproductive tract, bacterial culture of the uterine lumen, and full-thickness biopsy of the uterus. The patency of the uterine horn and uterine tubes might be determined by infusion of sterile saline solution, using the techniques developed for in vitro fertilization and embryo transfer. Laparoscopy and celiotomy are best performed during anestrus to fully appreciate persistent pathologic changes in the uterus.

# FEMALE INFERTILITY

An accurate history is critical to the evaluation of a female animal suspected to be infertile. When taking the history, the clinician should investigate the details of previous cycles, including the dates of onset of each cycle, the female's behavior during estrus, the dates and methods of previous inseminations, the fertility of the studs used, and the events following breeding (Box 56-3). A complete physical examination should be performed to identify (1) potential causes of infertility outside the reproductive tract, (2) other abnormalities that might adversely affect the health of the female or the pregnancy itself should conception occur, and (3) congenital and heritable defects that should exclude this female from a breeding program.

The reproductive tract is then examined. Mammary glands are carefully palpated to assess their size and consistency and the character of any secretions. The vulva is inspected to determine if there are structural abnormalities or any discharge. The labia are separated so that the vestibular mucosa and clitoris (in bitches) can be visualized. The uterus is palpated transabdominally. A vulvar discharge may be more apparent after abdominal palpation. The vestibule and posterior vagina should be palpated with a gloved finger in bitches of adequate size. Rectal palpation may help determine the extent of abnormal structures within the vestibule and caudal vagina.
